of BOW

■ Corrective treatment in spastic and atonic constipation aims to cooperate with Nature toward promoting reflex colonic peristalsis.

This cannot be accomplished satisfactorily by cathartic drugs, purging salines, distending bulk, trick foods, and "roughage", which irritate and over-stimulate the intestine. Mineral oil preparations likewise offer the disadvantage of leakage, and by hastening the current, interfere with digestion.

IDEAL TREATMENT

The persistent search for an agent which would encourage physiologic functional activity naturally and effectively in the treatment of the sluggish or irritated colon, results in Metamucil—an outgrowth of the mucin idea—clinically practical, easy to take, inexpensive and functionally a success.

SPASTIC COLON—

Metamucil produces a bland and lubricating effect which enables the food residue more readily to pass through the narrowed lumen

ATONIC COLON—

Metamucil aids by producing a soft, formed, plastic, mucilaginous, lubricating, non-irritating fecal mass

METAMUCIL

SEARLE

WHAT IS METAMUCIL? Metamucil is a purified, concentrated vegetable mucilloid prepared from the seed of *Plantago Ovata* (Forsk), freed of all solid particles, and held in dispersion with a specially prepared milk powder.

WHAT DOES METAMUCIL DO? Metamucil helps to promote and regulate intestinal peristalsis by providing the lubricant effect of the normal human secretion, supplying the bland, easily compressed bulk necessary for fecal propulsion.

A VALUABLE ADJUVANT IN PEPTIC ULCER

Although chemically unrelated to mucin, Metamucil is similar in physical characteristics. It has been found a valuable aid in the treatment of gastric and duodenal ulcer in this way: Metamucil forms a mucilaginous gel which renders the stomach contents less irritating to the ulcer crater; it is mildly acid adsorbent—reduces amount of alkali needed; it helps correct accompanying colonic dysfunction and pain.

ULCERATED COLON—

By mixing with and partially enveloping rough and undigested food particles, a soothing and protective effect is produced by the use of Metamucil (Searle)

Metamucil (Searle) is supplied in 1-lb. and 6-oz. containers.

MAKE A TEST

Metamucil is as easy to take as it is effective. We invite you to make a test—Free. The coupon is for your convenience in requesting sample and literature.

TRAUMATIC DUODENAL ULCER IN A 10 YEAR OLD BOY— <i>Jack Witherspoon, M.D.</i> - - - - -	135
--	-----

PUBLISHED MONTHLY BY THE SANDFIELD PUBLISHING CO.

Clinicians, bacteriologists and pathologists unanimously agree that, so far as possible, the alimentary-tract content of pathogenic bacteria and their harmful products should be reduced.

Alpha-Naphco, whether as such or in the jelly-form, by rigid and unbiased laboratory tests (on both man and animals) has been found to be a very potent preparation in reducing the number or inhibiting the growth of pathogenic organisms present in the lower bowel. No evidences of toxicity have been observed even when the preparations have been given in dosage far greater than called for clinically.

The preparation is dispensed as Liquid Alpha-Naphco Germicide and the Jelly of Alpha-Naphco in Enteric-Coated Capsules. Beneficial results, in-so-far as reduction of the number and kind of pathogenic bacteria are concerned, have been achieved by the daily administration of these products in suitable dosage.

No evidence has been brought forth that normal digestive functions are disturbed while Liquid Alpha-Naphco Germicide and the Jelly of Alpha-Naphco in Enteric-Coated Capsules are being exhibited.

The Manufacturer, a trained laboratory investigator, would appreciate Clinicians in Institutions as well as general practitioners, putting Liquid Alpha-Naphco Germicide and the Jelly of Alpha-Naphco in Enteric-Coated Capsules to actual test.

It would seem that these preparations are capable of acting favorably in chronic ulcerative colitis, amebiasis accompanied by the presence of dysentery-producing organisms, acute "Summer" dysentery of children, ordinary bacillary dysentery and kindred affections.

If applied for upon physicians' stationery or their prescription blanks, the Manufacturer is willing to forward a liberal supply of Liquid Alpha-Naphco Germicide and the Jelly of Alpha-Naphco in Enteric-Coated Capsules for actual trial. With the trial samples, data respecting research and clinical investigations also will be sent.

Enquirers Should Address

CAREL LABORATORIES

REDONDO BEACH, CALIFORNIA

NOTE:—These preparations are not and never will be offered through channels other than those concerned with the medical profession.

# For bland diet therapy, especially ULCER cases—PABLUM

**F**AR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.<sup>1</sup> "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

## Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

## Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."<sup>2</sup>

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly pre-cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. <sup>1,2</sup> Bibliography on request.

PUBLISHED MONTHLY BY THE SANDFIELD PUBLISHING CO.

“ . . . we know that in the infant and growing child alkali in excess of acid must be stored.”

**BUT—**

*Growth and Development of the Child, Part III, White House Conference on Child Health and Protection, New York, 1932, p. 213.*

## many diets are acid-forming

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), “. . . most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary.”

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

**INFANCY AND CHILDHOOD.** “Alkaline diets are essential for infancy where growth is rapid,” declares Shohl. He calculates the need as 10 cc. excess of 0.1 normal base per kilo per day.<sup>1</sup> Babies fed on breast milk stored an excess of base over acid, the range being from 31 to 56 cc. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.<sup>2</sup> Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.<sup>3</sup>

**PREGNANCY AND LACTATION.** Shohl states, “Pregnancy and lactation require additional alkali—a minimum of 150 cc. 0.1 N base per day.”<sup>4</sup> Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. “This may be some indication,” they say, “of the magnitude of the maternal needs exclusive of fetus.”<sup>5</sup>

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal<sup>6</sup>—offers a way to add muffins, cereal, puddings and similar “filling” foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins A, B, E, and G.

<sup>1-4</sup> Bibliography on request.

<sup>6</sup> Mead’s Cereal (Pablum in uncooked form) is also base-forming.

**MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.**

Pablum (Mead’s Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers’ yeast, iron salt and sodium chloride.

| Cereal       | Base | Acid |
|--------------|------|------|
| PABLUM       | 1.8  |      |
| Farina       |      | 11.0 |
| Oatmeal      |      | 12.9 |
| Wheat, whole |      | 11.5 |
| Cornmeal     |      | 5.3  |
| Barley       |      | 10.1 |
| Rice         |      | 8.1  |

Figures given in the above table are based on 100 grams of food and represent cubic centimeters of normal acid or base.

# For bland diet therapy, especially ULCER cases—PABLUM

**F**AR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.<sup>1</sup> "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

## Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly pre-cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. <sup>1,2</sup> Bibliography on request.

**MEAD JOHNSON & COMPANY - - Evansville, Indiana, U. S. A.**

## Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."<sup>2</sup>

Please enclose professional card when requesting samples of Mead Johnson products to cooperate in preventing their reaching unauthorized persons.

# Sunshine or Not—They Need Vitamin A

## Smaco CAROTENE-in-oil provides Vitamin A activity alone

Adequate summer sun may make added vitamin D in the diet unnecessary but it does not take the place of Vitamin A • The human body needs Vitamin A activity twelve months of the year, winter and summer, regardless of whether it is exposed to sunshine or

not. • Vitamin A activity in edible fruits and vegetables occurs only in the form of Pro-Vitamin A, (Carotene). • In prescribing Smaco Carotene-in-oil you are providing Vitamin A activity in the same form in which it occurs in fruits and vegetables.

PUBLISHED MONTHLY BY THE SANDFIELD PUBLISHING CO.

"... we know that in the infant and growing child alkali in excess of acid must be stored."

**BUT—**

**many diets are acid-forming**

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), "... most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary."

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

**INFANCY AND CHILDHOOD.** "Alkaline diets are essential for infancy where growth is rapid," declares Shohl. He calculates the need as 10 cc. excess of 0.1 normal base per kilo per day.<sup>1</sup> Babies fed on breast milk stored an excess of base over acid, the range being from 31 to 56 cc. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.<sup>2</sup> Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.<sup>3</sup>

**PREGNANCY AND LACTATION.** Shohl states, "Pregnancy and lactation require additional alkali—a minimum of 150 cc. 0.1 N base per day."<sup>4</sup> Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. "This may be some indication," they say, "of the magnitude of the maternal needs exclusive of fetus."<sup>4</sup>

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal\*—offers a way to add muffins, cereal, puddings and similar "filling" foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins A, B, E, and G.

<sup>1,4</sup> Bibliography on request.

<sup>2</sup> Mead's Cereal (Pablum in uncooked form) is also base-forming.

**MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.**

Pablum (Mead's Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers' yeast, iron salt and sodium chloride.

| Cereal       | Base | Acid |
|--------------|------|------|
| PABLUM       | 1.8  |      |
| Farina       |      | 11.0 |
| Oatmeal      |      | 12.9 |
| Wheat, whole |      | 11.5 |
| Cornmeal     |      | 5.3  |
| Barley       |      | 10.1 |
| Rice         |      | 8.1  |

Figures given in the above table are based on 100 grams of food and represent cubic centimeters of normal acid or base.

Decholin, (dehydrocholic acid), a true choleretic and practically non-toxic, is indicated when stimulation of liver cells to increase the secretion of bile is desired. It has been found distinctly valuable in functional hepatic insufficiency, in cardiac conditions associated with hepatic dysfunction and ascites, and in toxemias due to hepatic intoxication. Decholin may be given orally for prolonged effect, or may be administered intravenously as the sodium salt for prompt, intense action. Given by either route, profuse choleresis usually follows.

| Pears (Bartlett)       | 6%  |
| Pineapple (Sliced)     | 12% |
| Prune Plums            | 9%  |
| Raspberries (Black)    | 9%  |
| Raspberries (Red)      | 7%  |
| Strawberries           | 6%  |
| Fruit Combination      | 9%  |

Increase the choice of fruit in the low carbohydrate diet

### FOOD VALUE

Fruits packed in water without added sugar are shown by chemical analysis to have their carbohydrate content reduced from that of the fresh product. Lessening the carbohydrate content makes it possible to include these fruits in diets where fresh fruits might be prohibitive. We list the carbohydrate values of Cellu fruits here for convenience of comparison.

### CONVENIENT TO USE

Cellu Canned Fruits not only increase the variety in the menu but add much to the convenience of food preparation. Saccharine may be added to these fruits if desired.

# CANNED FOODS IN INFANT NUTRITION

## I. Evaporated Milk

No phase of human nutrition has been more intensively studied than has that of infant nutrition. As a result of numerous investigations, much valuable information concerning the nutritive requirements of infancy has been accumulated. In addition, the quantitative nutritive demands of early life have been established within reasonable limits.

Along with advances in our knowledge of the science of nutrition have come changes in the older ideas concerning infant feeding. It is now an accepted fact that properly modified cow's milk can successfully supplement breast milk—in fact, where necessity or expediency demands, cow's milk properly modified and properly supplemented, can meet

fully all nutritive requirements of infancy. As far as proper nutrition is concerned, the "bottled baby" of today starts on life's road with brighter prospects than did his fellow-being of a generation ago.

Evaporated milk is particularly well adapted to preparation of milk formulas for infant feeding. Numerous studies, laboratory and clinical, have demonstrated its nutritive values—ample practical medical experience has proven its worth in infant nutrition. From the wealth of available literature, we have selected the following concise summary which describes this canned food and outlines those characteristics by virtue of which it is held in such high esteem as an infant food (1).

### (1) J. Am. Med. Ass'n 97, 1890 (1931)

1. Evaporated milk is pure fresh cow's milk with approximately 60 per cent of the water removed by evaporation under reduced pressure.

2. Evaporated milk is equal to pasteurized milk in all important food values; it supplies those vitamins which milk can be depended on to supply and in practically equal quantity.

3. Evaporated milk is sterile and therefore is the safest milk obtainable; it cannot introduce pathogenic micro-organisms to induce diarrhea in infants.

4. Evaporated milk casein curd in the stomach has a finer granular and softer texture or structure than that produced from raw or pasteurized milk; it resembles in physical structure the curd of human milk.

5. The fat of evaporated milk because of the homogenization processing is more finely dispersed than the fat of ordinary milk and therefore it is more readily acted on by digestive enzymes.

6. Evaporated milk is more speedily digested than raw or pasteurized milk or milk boiled only a very short time.

7. Evaporated milk is usually less allergic than raw or pasteurized milk.

8. Evaporated milk is one of the most convenient and economical forms of milk for preparing infant feeding formulas.

9. Evaporated milk enables introduction of more milk in the diet because it is concentrated.

10. Evaporated milk is considered by many pediatricians to be the best form of cow's milk for preparing the baby's formula.

PUBLISHED MONTHLY BY THE SANDFIELD PUBLISHING CO.

# ON THE PAGES OF THIS JOURNAL

we have, during the past year, presented for your consideration the qualities of Irradiated Pet Milk which have proved it to be a valuable aid in the treatment of gastro-intestinal disorders.

Physicians who have considered these qualities and who have put Pet Milk to practical test have been convinced that it serves remarkably well in the therapeutic procedures in which milk is employed.

For the convenience of physicians who may not have given consideration to the use of Pet Milk, we present a summary of its outstanding qualities:

**1**—Pure, whole cow's milk concentrated to uniform double-richness—a quality which facilitates the inclusion of more milk in the diet.

**2**—Free from all bacterial life—a safeguard against illness or intestinal irritation from this source.

**3**—Readily digestible, because of the formation of small, soft, non-irritating curds.

**4**—Especially suitable for the patient in whom milk causes allergic reactions—the advantage being due to alteration of the whey proteins.

**5**—Irradiated with ultra-violet rays, it contains appreciably more vitamin D than ordinary milk.

**6**—Costs less than other forms of milk, often only half as much as bottled milk.

We should be glad to send samples for trial purposes, and literature containing additional information.

PET MILK COMPANY, 1446L Arcade Bldg., St. Louis, Mo.

# The **Larostidin treatment**

## OF PEPTIC ULCER YIELDS EXCEPTIONALLY GOOD RESULTS

Four out of five cases, if put on the Larostidin treatment right away, will not have to be subjected to alkali medication or dietetic restriction.

*This is what you can confidently expect Larostidin to do for a gastro duodenal ulcer patient:*

- no interference with business or social duties
- freedom from all other medication
- relief of pain within a few days
- freedom from other symptoms in one week
- tolerance for regular diet in 5 to 10 days
- in most cases, a substantial gain in weight.

The evidence in favor of Larostidin should make it the first thought in peptic ulcer. No other treatment offers all these advantages.

*Issued in: Ampuls, 5 cc. Cartons of six (6)*

**HOFFMANN-LA ROCHE, Inc.**  
Roche Park • Nutley • N. J.

### THE EVIDENCE HAS PILED UP

During the last 12 months at least 58 articles on the Larostidin treatment of peptic ulcer appeared in the medical literature. The leading articles in British and American Journals were:

Bulmer, E.: *The Lancet*, 1931, 2: p. 1276-1278.

Volini, I. F. and McLaughlin, R. F.: *The Medical Record*, 1935, 141: 361.

Smith: *The British Medical Journal*, 1935, No. 3890, p. 154-159.

Craig: *The British Medical Journal*, 1935, No. 3896, p. 478.

Ryan: *The British Medical Journal*, 1935, No. 3899, p. 602-603.

Eads: *American Journal of Digestive Diseases and Nutrition*, 1935, II: 426.

Rafsky: *Medical Record*, 1935, 142: 289.

Ahl: *The Military Surgeon*, 1935, 77: 216.

Physicians are invited to ask for a complete bibliography.

# CANNED FOODS AND THE PUBLIC HEALTH

## I. The "Ptomaines"

• Many requests received for further information on canned foods have inquired as to some of the public health aspects of this class of foods. We appreciate the frank interest of our readers in this subject about which so much misinformation exists. We are glad, therefore, to devote this discussion, as well as subsequent ones, to the most popular of the lay misconceptions concerning the wholesomeness of commercially canned foods.

Some laymen hold the belief that canned foods, in some mysterious manner, develop "deadly ptomaines" within the can and hence the consumer of such foods stands in danger of "ptomaine poisoning". In the light of modern knowledge, this belief is ludicrous; it probably had its origin in the old "ptomaine theory" of food poisoning, now so thoroughly discredited by modern medical authorities (1).

Between the years 1870 and 1880, a large number of substances were obtained from protein material which had undergone bacterial putrefaction. These substances were aptly called "ptomaines", from the Greek "ptoma" or "dead body". Toxicologists of the day ascribed marked toxic properties to the new found ptomaines, chiefly by injection studies rather than by feeding tests.

The science of bacteriology was then in its

infancy—the true causes of food infection or intoxications were not known. Consequently, the discovery of the ptomaines, with their alleged toxic properties, permitted the convenient diagnosis of "ptomaine poisoning" for all illnesses following the ingestion of foods. Today, we know that such illnesses usually result from the ingestion of food which had been infected by certain bacterial groups, and not from protein degeneration products such as ptomaines (2, 3).

One authority has stated that "ptomaine poisoning is a good term to forget" (4).

To this we might add that it would also be well to discard the old, unfounded belief that foods in the tin can develop substances hazardous to health.

Canned foods are merely selected foods which, after proper preparation, are sealed in hermetic tin containers and given a heat process calculated to destroy pathogenic and spoilage organisms which might be present on the raw foodstuff. The hermetic seal prevents future infection of the food by such organisms and insures its preservation and wholesomeness.

Such are the simple facts. The cooperation of the medical profession is earnestly solicited in combating the ludicrous, yet widespread, lay prejudice against commercially canned foods.

# SECTION I—*Clinical Medicine: Diseases of Digestion*

## Diarrhea

By

JOHN L. KANTOR, M.D.  
NEW YORK CITY, NEW YORK

### DEFINITION

**D**IARRHEA is a clinical syndrome in which the stools, generally increased in frequency, lose their normal form and assume a mushy or watery consistency. The changed appearance of the dejecta is due to their increased fluid content resulting from insufficient water absorption, abnormal exudation from the bowel wall and hastened transport through the intestine. Accelerated passage through the distal colon is essential for the occurrence of diarrhea since increased motility in the upper bowel segments alone will not suffice for the production of this symptom. Such a "diarrhea without diarrhea" may actually occur in mild cases of simple colitis, and has even been described in cholera—so-called cholera sicca (Schmidt) (16).

### CLINICAL PICTURE

The number of stools varies from two or three a day to one every few minutes; the consistency from mushy to liquid. Admixtures of undigested food, mucus, blood, or pus may be present. Abdominal distress, cramps, and flatulence are common. Sooner or later, the rectum rebels and proctitis supervenes. The chief systemic manifestations of severe, *acute diarrheas* are rapid dehydration and a toxemia which may lead to collapse. *Chronic cases* are marked by gradual but no less profound nutritional disturbances. Among these are emaciation and anemia from loss of nutriment including vitamins, as well as skeletal changes (osteoporosis, deformity, dwarfism) from loss of calcium salts when steatorrhea is prominent.

### CLASSIFICATION

In the present state of our knowledge, it is impossible to offer an etiological classification of the diarrheas. All that can be attempted is a crude division into *functional* and *organic* groups, as indicated by Table I. The organic cases are characterized by the presence, the functional by the absence, of a demonstrable lesion of the intestinal mucosa. In organic diarrheas the stools contain pus, blood, infectious bacteria, or parasites; the mucosal lesions may be seen through the proctoscope; there may be anemia, fever, emaciation, dehydration or collapse. In the functional diarrheas these features are absent. However, two important points must be kept in mind, first, that

long-continued functional disorders may lead to organic changes, second, that even extensive lesions (ulcers, tumors) may be present without the occurrence of any diarrhea whatever.

### LOCATION OF INTESTINAL CHANGES

A word may be said as to the portion of the intestine involved in diarrhea. The rectum may be the seat of infection, ulceration, or neoplasm. The colon is involved in the dysenteries, in neoplasms, in idiopathic ulcerative colitis and in simple colonic instability. The small intestine is specifically involved in typhoid fever, in the bacillary dysenteries, including cholera, in tuberculosis, and in the regional inflammation described by Crohn (3). A non-specific affection of the small intestine is called an enteritis, but the alimentary canal on either side is usually involved as well, so that one really has to deal with a gastro-enteritis, or an entero-colitis, or in some cases with a gastro-enterocolitis. All these varieties seem to be more common in children. In such cases, it has been suggested that the inflammation may result from an increase in the virulence of microorganisms normally present but ordinarily harmless, or by the ascent of lower intestinal bacteria into the upper bowel with resulting "wall infection."

### INCIDENCE

The incidence of diarrhea varies greatly with general living conditions and particularly with the effectiveness of sanitation. Diarrheal diseases have long been dreaded as the scourge of armies. In our Civil War, the hospital admission rate was 876 per 1000, the death rate 10 per 1000. In the Spanish American War, the admission rate was 402, the death rate 2, while in the World War with little exposure, the rates for our troops were 35 and 0.1 per 1000 respectively. Unfortunately, correspondingly exact figures for the incidence of these diseases in civilian life are not available. However, the 1933 outbreak of amebiasis which originated in Chicago that summer resulted in some 800 cases reported throughout the country by the following February; and this year's epidemic of bacillary dysentery in the metropolitan area involved between 1500 and 2000 cases, according to some authorities.

It is well known that infants are more affected by diarrheal disease than adults and that the incidence of diarrhea in hospitals is different from that in pri-

|                                                                       | b. regional ileitis                                |

vate practice. It is regrettable that hospital statistics are so meager. Apparently, the only article of importance on this subject originating from a hospital experience was published 21 years ago by Richard Cabot and Haven Emerson (2). It is based on a post mortem and clinical study of 640 cases.

Statistics derived from the private practice of any one individual are notoriously personal and cannot be expected to apply too precisely to the experience of another physician. Yet there is a unity of viewpoint and a continuity of observation that may make their presentation of some interest to others. Thus, in an unselected series of 3880 private patients complaining of various digestive troubles during the past 18 years, I observed 390 cases of diarrhea, an incidence of 10 per cent, with a mortality of 2.5 per cent. The frequency of the various varieties is presented in Table II. In 12 cases, the type of diarrhea remained undeter-

ined. In this series there were no cases of pellagra or proven pancreatic insufficiency in the functional group, or of poisoning with heavy metals, of cholera or of typhoid in the organic varieties.

#### DIAGNOSIS

The diagnosis of diarrhea is made essentially from the stool examination, but it is supplemented by proctoscopy, roentgen investigation, and the usual methods of history-taking and physical examination.

A mere naked eye inspection of the stool suffices to show whether the dejecta consist entirely of fecal matter or whether various unnatural constituents are present. Mucus suggests irritation, pus inflammation, blood ulceration of the intestinal mucosa, whereas a copious watery flux implies a serious loss of tissue fluids through this semi-permeable membrane such as one encounters in the so-called compensatory diarrheas

TABLE II  
TYPES OF DIARRHEA IN 390 PRIVATE CASES

| <i>Functional</i>                           |     | <i>Organic</i>                   |    |
|---------------------------------------------|-----|----------------------------------|----|
| 1. Colonic instability ("nervous diarrhea") | 210 | 1. Idiopathic ulcerative colitis | 41 |
| 2. Gastrogenous                             | 70  | 2. Tuberculosis                  | 12 |
| 3. Simple or environmental                  | 22  | 3. Post-dysentery                | 10 |
| 4. Idiopathic steatorrhea                   | 5   | 4. Regional ileitis              | 5  |
| 5. Allergic                                 | 5   | 5. Carcinoma of rectum           | 4  |
| 6. Compensatory                             | 4   | 6. Acute bacillary dysentery (?) | 3  |
| 7. Malabsorption                            | 2   | 7. Amebic dysentery              | 3  |
| 8. Endocrine                                | 2   | 8. Rectal stricture              | 1  |
| 9. Putrefactive                             | 2   | 9. Amyloid disease               | 1  |
| 10. Fermentative                            | 2   | 10. Trichomonas                  | 1  |
|                                             | 324 |                                  | 81 |

Functional, 324; Organic, 81; Undetermined, 12; Total, 417; Counted twice, 27; Net total, 390.

or in cholera. All the dysenteries exhibit blood and mucus, but the typical amebic stool differs from that of bacillary dysentery in that the fecal element predominates in the former. The presence of undigested food suggests an enteritis.

Information may also be obtained from the smell of the dejecta. Intestinal dyspepsias of the putrefactive and of the fermentative types can be differentiated by the corresponding putrid or sour odors, pancreatic insufficiency can be diagnosed at a distance by the high and penetrating aroma of rancid putrefaction, whereas the diarrhea of uremia is said to be characterized by the familiar evidence of ammonia. On the other hand, the "rice water" stools of cholera are as odorless as the bland discharges of an ileostomy.

The demonstration of *excessive fat* in the feces is important in the diagnosis of the various forms of steatorrhea. The well known bulky gray and greasy stools of gross pancreatic disease are due to the enormous output of free fat in this condition. In sprue and celiac disease, the stools are more likely to be frothy or soapy in appearance, since the fat is not present in the neutral state but rather in the form of fatty acid crystals and soaps. A simple microscopic examination is helpful. A small amount of feces is mixed with 30% acetic acid on a slide under a cover slip and then heated until the soaps and crystals are melted. On cooling, these take the form of clumps or globules which may be readily stained with Soudan III and thus identified.

Laboratory examination is necessary for the identification of the specific dysenteries. However, the laboratory (i.e. the microscope) must be brought to the bedside for the demonstration of the motile forms of the *endameba histolytica*. The material examined may be obtained either from the stool itself in the form of a clump of blood-streaked mucus, or by scraping the ulcerated bowel mucosa directly under proctoscopic visualization. If the acute phase is over and constipation is present, a fresh fluid specimen may be obtained by saline catharsis. It should be noted that formed feces contain only the encysted forms of the parasite. Such stools may be transported long distances for examination, but for accuracy this investigation requires a specialized technique.

In the bacillary diarrheas bacteriologic studies are essential for the identification of the specific agents of cholera and the various forms of dysentery. Unfortunately, it requires considerable time for a complete bacteriologic diagnosis. However, the comma bacillus can be fairly well identified on smears, and Haughwaut (9) has suggested that a differential diagnosis between bacillary and protozoal dysentery can be made in the earliest stages by a rapid examination of the fixed and stained exudate from the intestine. Later in the course of the bacillary infections (that is after the first week) agglutinins appear in the blood and can be utilized as aids to positive diagnosis.

Bacteriologic examination is also necessary for purposes of epidemiologic information and control, in identifying the specific organisms (paratyphoid enteritides group, and certain staphylococci) now believed to be the etiologic factors in those cases of food poisoning (popularly called "ptomaine") which chiefly affect the alimentary tract (7,13).

Proctoscopic examination is of value in the demonstration of new growths, impactions, ulcerations and inflammatory conditions in the rectum and lower pelvic colon. Ulcerative colitis usually gives a fairly characteristic picture but unfortunately it cannot always be positively distinguished from amebic dysentery.

Roentgen examination serves to confirm the diagnosis and indicates the extent of the involvement in advanced (not early) ulcerative colitis. It is the best available method (though not pathognomonic) for the diagnosis of ileo-cecal tuberculosis and of regional (terminal) ileitis. It may also be of value, according to some authorities, in identifying the cecal involvement of amebic dysentery. The characteristic dilation of the colon in cases of idiopathic steatorrhea, a finding which has not been adequately stressed, can best be demonstrated by an opaque enema. The usefulness of the x-ray in impactions and neoplasms needs no emphasis. Studies of the unstable colon are best carried out by the roentgen method. For a complete roentgen investigation both the progress meal (especially the "nine-hour" observation) and the opaque enema are desirable.

Finally, the history and other general and special examinations of the patient should not be neglected. By these means one may obtain information as to exposure to epidemic diseases, the ingestion of spoiled food or of drugs or poisons, the occurrence of diarrhea in other members of the family, individual idiosyncrasies or allergic states, unbalanced, restricted or insufficient diets, low or absent gastric acidity, susceptibility to heat or chilling of the body, the existence of chronic illness such as Graves' disease or renal insufficiency, previous abdominal operations, the possible presence of intestinal new growth or fecal impaction, and other similar factors of etiologic, epidemiologic or diagnostic import.

## SPECIAL VARIETIES

### A. Functional

*Simple or environmental* diarrhea may occur in any normal individual whose intestine is exposed to some unusual irritant. The most common cause is food which is either too coarse, too cold, or laden with bacteria already described as responsible for food poisoning. Cathartics, fecal impactions, and chilling of the body surface\* (15) may be cited as other causes. Simple diarrheas are very common but the condition is so mild and shortlived that most cases probably never come to the doctor.

*Anaphylactic or allergic* diarrhea is not always easy to prove to one's satisfaction. We could be sure of only 5 cases. Some patients were sensitive to but one food, others to many. Fish and veal seemed responsible in two patients. Other protein offenders were oatmeal, eggs, eggplant, beets and bananas. Milk and corn raised havoc in so many varieties of diarrhea that they could hardly be regarded as specific in the allergic reaction.

*Gastrogenous* diarrhea is common, 68 of our cases belonging to this variety. Achlorhydria was present in 57 cases, delayed gastric emptying in 7, and malfunctioning gastroenterostomy in 4.

\*One of my patients who had been a British soldier stationed on the Island of Malta told me that the sentries were always changed as soon as the cold, damp sirocco wind came up from Africa in the afternoon in order that all hands might have an opportunity for a hasty visit to the latrine.

*Putrefactive and fermentative* diarrheas are probably associated with an enteritis and result from a "wall infection" as already suggested. Intestinal fermentation was originally described by Adolf Schmidt (16) as "Gährungsdysepsie." In this country little attention was paid to this variety until the recent study by Althausen and his collaborators (1) on "Carbohydrate-intolerance and Intestinal Flora," in which 50 cases were reported. This is still a rather ill-defined group in my opinion and may ultimately prove to be not so far removed from the idiopathic steatorrheas to be described later.

*Endocrine* diarrheas may be due to overactivity of the thyroid or hypoactivity of the adrenal gland. In one patient, the diarrhea was so definitely menstrual as to suggest the possibility of a gonadal influence. Our experience with this group is unfortunately very limited.

*Idiopathic steatorrhea* (sprue, non-tropical sprue, celiac disease) is probably not so rare in this climate as has been supposed. Attention has recently been called to this fact, chiefly by the work of Holmes and Starr (10) of Chicago, Haas (8) of New York, and Hess Thaysen (18) of Copenhagen. Since free fat does not appear in the stools, but only fatty acids and soaps, the movements are not greasy as in pancreatic disease but are more likely to be frothy and acid in reaction, as in fermentative diarrhea.† There is an associated intolerance for starches, except banana starch for some unexplained reason. The co-existence of meteorism with diarrhea is a striking clinical characteristic of this disease. The excretion of increased amounts of soaps causes a steady drain of calcium salts with the result that nervous irritability increases and skeletal changes supervene. These latter may result in infantilism or bony deformities. In this way a distant resemblance to rickets is suggested. We have record of five probable cases of idiopathic steatorrhea. One of these patients died following hemorrhage from a duodenal ulcer.

*Pellagra* is not represented in this series. My only experience with the disease was a limited one in a Southern camp during the World War. The patients promptly recovered on a well-balanced diet. The disease is "endemic" where the diet is lacking in the specific pellagra-preventive ( $B_3$  or G) vitamin found in meat, eggs, milk and yeast. In this locality one should be on the lookout for cases due to faulty absorption produced by intestinal strictures, new growths or other similar interfering factors.

*Compensatory* diarrheas are rare but interesting forms which are assumed to occur when the usual avenues of excreting metabolic or other toxins prove inadequate. Renal insufficiency, skin burns and the universal breakdown of senility are usually cited as causative factors. Thus, older clinicians (17) have reported cases in which diarrhea has acted as a safety valve in preventing an impending uremia. That the intestine actually can excrete large amounts of retained nitrogenous substances recently has been shown by Williams and Dick (19). Our four patients presumably belong to the senile group, inasmuch as no other cause for the diarrhea (except achylia in one instance) was apparent.

*Deficient* absorption from resection of the small intestine seemed to cause diarrhea in two patients. The condition appears to be self-limited in proportion to the capacity of the remaining bowel to compensate for the loss of absorbing membrane.

*Colonic instability*, so-called "nervous diarrhea," was by far the most common variety observed in this series (11). The 212 cases in this group exceeded all the other forms put together. The usual cause is autonomic or emotional instability, but vicious bowel habits, especially the cathartic habit, must be held responsible in many cases. Alternating constipation and diarrhea are a common complaint and the constant recurrence of this sequence well illustrates the abnormal excursion in autonomic imbalance from the extreme of spasticity on the one hand to that of irritability on the other.

#### B. Diarrhea Due to Organic Lesions

*Toxic* diarrheas may result from exogenous or endogenous causes. Among the former is poisoning with heavy metals such as mercury, arsenic, lead and bismuth. During the vicarious excretion of these substances by the intestine, the mucosa undergoes ulceration. Endogenous causes are illustrated by the toxins of uremia, sepsis, and burns. Ulcerations have been described in these conditions. Toxic diarrheas are not represented in our series of cases.

*Infectious* diarrheas also fall into two classes, specific or primary, and non-specific or secondary. Among the former are the bacillary diarrheas. Tuberculosis was diagnosed in twelve cases, all with advanced pulmonary involvement. Three of these patients are known to have died. There is no instance of primary intestinal tuberculosis in this series. A diagnosis of acute dysentery was ventured in three cases all of which began with a bloody diarrhea and resolved spontaneously after a short course. Although unconfirmed bacteriologically, it was assumed that these were probably cases resembling the mild Sonn  infections recently described by Felsen (4, 5). A fourth case was that of an intern who was a victim of a hospital epidemic of paratyphoid.

Typhoid diarrheas are not included in this group, but are sufficiently familiar to the reader not to require description. Cholera is a disease not seen in these parts. The dramatic speed with which it strikes is well illustrated in an anecdote related by an officer of the U. S. Army, who in 1902 was stationed with an infantry regiment in Luzon, Philippine Islands. He was assigned as counsel to defend a military prisoner before a court marshal which was to convene at 1 P. M. on a given date. At 10 A. M. that morning, the officer interviewed his client who was apparently in good health. At about 10:30 this soldier and half his company came down with cholera. By 3 P. M. the soldier was dead. The mortality among those affected was 30%. The mode of infection in this instance was traced to the company cook who, finding the breakfast coffee too hot, cooled it off by diluting it with water from a nearby stream. The breakfast was served at 6:30 so that the incubation period in this case was 4 hours, and the total duration of the disease but a half day longer.

The second subgroup of infectious diarrheas is non-specific or secondary in nature. They are conceived as resulting from any long-continued functional

†The possible relationship of sprue to some of the so-called fermentative diarrheas already has been mentioned. One wonders how many of the latter have an associated steatorrhea as well. Further work along these lines is desirable.

or organic condition in which the dominant rôle is now played by a superimposed infection with the original factor either entirely eliminated or set well in the background. In this group have been included one case of rectal stricture, as well as nine cases of persistent diarrhea, now presumably non-specific. The latter gave a very clear history of previous attacks of bacillary dysentery in places where the disease is believed to be endemic. Thus, three patients contracted the infection in Russia, and one each in China, France (wartime), Greece, Spain, Peru and Georgia. Since, according to Felsen (6), the ulcers of bacillary dysentery heal by the formation of granular tissue *without* new gland restoration, it seems proper to class these cases with the organic group.

*Parasitic* diarrheas in this locality are mostly protozoal, and especially amebic. It should be kept in mind in this regard that not all cases of amebiasis show diarrhea; and the present "epidemic" has taught us that the disease may assume unusual forms, resembling appendicitis or even pneumonia. Three proven instances of amebic diarrhea occur in our series. One case presumably due to trichomonas is also included.

*Necoplasms* of the lower bowel, especially of the rectum, are at times associated with diarrheal discharges. The movements, however, are not primarily fecal, but represent blood, pus and tissue detritus.

*Amyloid* diarrhea is represented by one probable case in which the terminal phase of a long drawn-out post-partum sepsis was marked by a constant intestinal flux. Unfortunately, there was no opportunity to confirm the diagnosis post-mortem.

*Colitis gravis* (so-called "idiopathic ulcerative colitis") furnished the largest number (41) of organic cases in this series. Again, it should be mentioned that not all forms of this disease are accompanied by diarrhea. Clinically it has seemed helpful to distinguish such sub-varieties as ulcerative, purulent, polypoid and indurative. Skin, joint and mucosal complications are often troublesome. The course is characterized by remissions and exacerbations. Four of the cases in this series went on to a fatal termination.

*Regional ileitis* was accompanied by diarrhea in 5 cases. The diarrhea may originate in the involved terminal ileum, but it may also be caused by the colitis which seems so regularly to accompany this condition.

The "*undetermined*" group consists of 12 cases in all but one of which adequate study was not possible. The one exception was a case of long standing diarrhea in which every diagnostic test proved negative, including repeated search for amebae by expert protozoologists. Fortunately, however, the patient made a complete recovery after a course of anayodin.

## TREATMENT

### A. General

*Rest.* General body rest is the first measure to institute in the treatment of diarrhea.

*Diet.* (1) All foods and drinks should be served hot. Hot tea and hot fruit juices are usually well taken. (2) The Schmidt intestinal diet is the best regimen for all simple diarrheas. (3) Milk is not well borne in the majority of patients. (4) Meat is usually well tolerated. (5) Roughage must be avoided (no raw fruit or vegetables) and small feedings are better than are large ones. (6) Raw apples, in scraped

form, have been shown by Moro (14) to exert a specific effect on the diarrheas of children. (7) In grave cases, especially when food cannot be taken by mouth, the parenteral administration of fluids in adequate amounts is a life saving measure.

*Drugs.* Generally speaking, these are to be avoided as much as possible. (1) Castor oil may be given at the beginning of a diarrhea which is due to ingested irritants. In the specific dysenteries this drug is recommended as a detoxicant. (2) Bulky, inert chemicals such as bismuth subcarbonate, barium sulfate, and kaolin are used to coat inflamed mucosa and bring down bacteria by "adsorption." To be really effective, these drugs must be used in tablespoon doses. (3) Calcium salts, such as the carbonate or gluconate, may be prescribed to replace calcium loss and to lessen transudation. (4) In desperate cases, resort must be had to opium.

*Local treatment.* Colonic irrigations are not advocated as a routine. In rectal tenesmus, however, considerable relief may be obtained by irrigating the rectum with hot, bland fluids through a return flow rectal (not colonic) irrigator of the Kemp type.

### B. Special

*Simple or environmental* diarrhea. Most cases are self-limited. If the irritant is still believed to be present a quick purge may be administered.

*Anaphylactic* diarrhea. The situation is somewhat similar to the preceding except that the patient is already sensitized to some foreign protein. Treatment involves the identification and avoidance of, or immunization to, the offending material.

*Gastrogenous* diarrhea. When achlorhydria is present the diet should undergo appropriate modification and HCl therapy should be instituted. For the cases with delayed gastric emptying the stomach should be treated primarily. This usually involves feeding in proportion to the gastric emptying power, frequent aspirations of old residues followed by lavage, alkalies when indicated, and finally, gastroenterostomy in advanced cases.

*Putrefactive* diarrhea is treated by initial castor oil catharsis and by the exclusion of foods which introduce putrefactive material into the intestine. In practice this means the administration of a strict carbohydrate diet to which proteins are added very gradually. According to the literature (12), di-hydranol should be effective in this condition.

*Fermentative* diarrhea is treated on the opposite plan, with a regimen somewhat similar to that used in diabetes, except that all rough and raw foodstuffs are eliminated. Owing to the possible relation of this variety to sprue, some of the principles of treatment outlined under the latter head would seem applicable here as well.

*Endocrine* diarrheas. The diarrheas of both Addison's and Basedow's disease are said to be controlled by rectal injections of epinephrin. Twenty-five drops of the 1:1000 solution in 200 c.c. of water are recommended for this purpose.

*Pancreatic* diarrhea is controlled either by large doses of pancreatin powder (30 grains 3 times daily) or, this failing, by fresh pancreas obtained directly from the abattoir.

*Sprue, non-tropical sprue, and celiac disease.* The diet is most important. Whole milk, fat and carbohydrate must be completely eliminated at the beginning of most severe cases. Protein is well tolerated, as is protein milk. Bananas and banana powder and strawberries are exceptions to the general rule and can be taken in large amounts, sufficient to sustain life alone. As many as 12 bananas and 3 quarts of strawberries may be fed daily even to depleted patients. The building up of the diet requires great individualization and much patience. The danger lies in adding too many different articles too quickly. Vitamin therapy is stressed by the most recent investigations. Vitamin B<sub>12</sub> (G), found in liver, yeast, and wheat germ is utilized. The dosage, according to some, may have to exceed that necessary in pernicious anemia. If sufficient amounts cannot be given by mouth, liver extract must be administered parenterally. In addition to B<sub>12</sub>, vitamins A and D, found in cod liver oil, are recommended. For the anemia, large amounts of iron, and for the osteoporosis and nervous irritability, substantial doses of calcium may be required. In my opinion parathormone should be administered with caution in this condition.

*Pellagra.* A high protein diet with liberal intake of vitamin B<sub>3</sub> (G) is recommended for this disease.

*Colonic instability ("nervous diarrhea").* Only a comprehensive plan of management can be successful in these cases. Vicious bowel habits must be eradicated, normal colon function must be restored and the autonomic nervous instability of the patient controlled as far as possible by all the methods at our disposal, such as rest, relaxation, sedation and common sense psychotherapy.

*Compensatory diarrheas.* These should be encouraged, rather than suppressed, since the flux tends to prevent the development of grave complications. Only in case the diarrhea leads to a permanent secondary (inflammatory) intestinal derangement should control measures be instituted. Exactly the same principles apply to the management of the toxic diarrheas.

The *infectious* diarrheas. (a) *Cholera.* Prophylactic vaccination was tried out during the World War and is said to have been effective. Active treatment is directed toward overcoming the collapse associated with the rapid dehydration and toxemia. For this purpose, practically continuous inflow of fluids by vein and subcutaneously is essential. Rogers recommends a hypertonic solution of sodium, calcium, and potassium chloride intravenously and the frequent administration of potassium permanganate pills by mouth.

(b) *Bacillary dysenteries.* Fortunately, the grave Shiga type is not seen here. For this form, an anti-toxic serum is available. The specific dysenteries which are likely to be encountered in this part of the world belong to the Flexner strain or to similar relatively mild organisms such as the Sonn . Specific bacteriophages are now available. Felsen prefers the rectal route of administration unless the diarrhea is too intense, when the intravenous method is required. This treatment is most likely to be efficacious in the first week of the disease. For elimination of the toxin, daily castor oil catharsis is recommended. Fluids must

be administered parenterally when necessary.

(c) *Tuberculous enteritis.* There is no specific treatment. Opium is required in the severe cases. Calcium gluconate intravenously may help some patients.

*Amebic dysentery.* Active treatment is based on the use of three drugs, ipecac, arsenic, iodine, in various forms and under various trade names. It is believed that ipecac attacks the parasites in the tissues, whereas the other two drugs kill the amebae on the intestinal surface. A fairly representative therapeutic program is as follows: (1) Emetine hydrochlorid 1 grain is given hypodermatically each day for 10 days, but not longer on account of the danger of toxicity. During the same period one 10 grain tablet of aluminum salicylate of ipecac ("aleresta") is given 3 times a day. (2) Next follows a week of rest and observation of the stools. (3) Following this comes a week of treatment with either arsenic or iodine. If the former is selected stovarsol (acetarsone) is administered in the form of 0.25 gram tablets 3 times a day. If iodine is preferred anayodin (chiniofon) pills, 4 grains each, are given 3 times a day for 8 days, or in any other dosage till a total of 96 pills is taken. It should be mentioned that anayodin produces an initial diarrhea. These measures usually suffice. If amebae persist in the stools, the dose of anayodin should be cut in half and the drug administered by rectum. For this purpose 200 c.c. of a warm 2 per cent solution should be given as a retention enema each day for 10 days.

*Colitis gravis, idiopathic ulcerative colitis.* Since the etiology is undecided, a specific therapy is lacking. The importance of general supportive measures such as rest and adequate feeding is obvious. Much can be accomplished with diet in the suppurative variety (pus stools, fever). Here a strict protein regimen agrees best. The meals should be built up of meat, fowl, fish, sea food, eggs, gelatin, meat soups, tea and hot fruit juices. Butter is permitted and saccharin should be used for sweetening. After the stools become formed and the fever drops, various starches may be added, beginning with the finer processed flours such as Robinson's "patent barley."

In the hands of some careful observers, the use of autogenous sera in acute cases and of vaccines in the chronic stages gives good results. In our experience improvement and even remission may occasionally be obtained from the use of small (300 c.c.) whole blood transfusions. These may be repeated weekly for about 6 weeks.

As in all dehydrations liberal saline-glucose infusions are indicated. Opium is unavoidable in bad cases. Ileostomy may be tried but though it seems to give temporary relief, it does not prevent the progress of the disease with its numerous crippling complications. On the whole, the present treatment of this condition is far from satisfactory.

*Leitis.* For the cases seen to date, surgical therapy is indicated. The results are satisfactory.

## RECAPITULATION

This presentation may be condensed in the form of the following rough rules of procedure for the management of a case of diarrhea in this locality:

1. Decide whether the condition is functional or organic. Look at the stool. If blood is present the diarrhea is probably organic.

2. Make an immediate decision about the initial feeding plan. For mild or functional cases, prescribe the Schmidt diet without milk. For the more severe cases, give only hot fluids as tea or fruit juices, but avoid milk. In the still graver forms (in this locality chiefly in infants) maintain the tissue fluid level by parenteral saline-glucose injections.

3. In all recent, bloody diarrheas make an urgent differential diagnosis between amebiasis, bacillary dysentery and idiopathic ulcerative colitis. If the diarrhea has persisted for over two weeks, a bacillary origin can be regarded as the least likely of the three in this community.

4. If you have reason to suspect amebiasis in the acute phase, bring the microscope to the patient and not the stool to the laboratory. Scrapings of bowel wall through the proctoscope give the best material.

If the diarrhea has ceased, produce a watery stool with a saline laxative. Look for active amebae with typical pseudopodial movements. Do not waste time looking for cysts unless you are a first class protozoologist.

5. If you suspect bacillary diarrhea (in this locality) have the stools cultured in the first week and have the blood tested for immune bodies in the next two weeks. Later in the disease these tests are seldom worth the trouble.

6. After excluding the specific dysenteries you may proceed more leisurely to the diagnosis and treatment of the chronic functional and organic conditions.

7. In recurrent diarrheas, especially when alternating with constipation, remember the frequency of colonic instability and the importance of restoring normal bowel function.

8. In all obscure chronic diarrheas keep in mind the possibilities of achylia gastrica and idiopathic non-tropical sprue, and make appropriate diagnostic and therapeutic investigations.

## Constipation

By

HENRY JAMES SPENCER, A.M., M.D.\*  
NEW YORK CITY, NEW YORK

**C**ONSTIPATION is a SYMPTOM and not a DISEASE.

A definition of constipation necessarily is rather elastic but it considers the elements of frequency of evacuation, volume, consistency and rate of transit through the intestines of the fecal mass. Fundamentally, constipation is undue and habitual delay in the evacuation of fecal wastes, but in defining the term "undue delay" again the factors of frequency of dis-

charge, volume, consistency and rate of transit must be observed and evaluated.

In order correctly to observe and evaluate these factors one must know something of the development, anatomy and physiology of the colon and other related parts and properly to deal with disturbed anatomy and physiology he must also know how the disturbing factors produce their effects. He then may hope to correct conditions and counteract factors which cause constipation. The following discussion is a brief presentation of the essential facts and some of the known disturbing factors including their mode of action.

\*Visiting Physician and Director, Second (Cornell University) Medical Division, Bellevue Hospital.  
Submitted November 5, 1931.

Finally suggestions are made regarding the correction of certain conditions and the combatting of others having to do with constipation.

### ANATOMIC CONSIDERATIONS

The colon is derived from the hind gut. At an early age the cecal bud appears at the junction of the small and the large intestine. Later it forms the cecum and the appendix. The whole gut lengthens, loops upon itself and undergoes a rotation which brings the colon into its well known, usual position. There is a concomitant descent of the cecum which usually (88%) carries it to the right iliac fossa. Both rotation of the colon and descent of the cecum may fail to occur. These facts account for abnormalities of location of the colon and of its relation to other viscera, some of which anomalies may promote constipation. At times the colon may lengthen to a degree where the length itself favors constipation.

The cecum is the widest part of the colon and its haustra are wide and shallow. It is separated from the ascending colon by an especially deep haustrum. The cecum and the descending colon muscularly are the weakest portions of the large intestine. The transverse colon exhibits the deepest haustra. The descending colon and the recto-sigmoid have the most powerful muscles. The fully developed colon ranges from 150-210 cm. (60-84 inches) in length. All measurements of length and diameter of intestines are approximate because the muscular tone constantly is changing and with it change the length and diameter of the organ. The capacity of the colon is between 1500 and 2500 cc.

The effective lumen of the colon roughly is about a third of its apparent cross-area, due to the transverse inter-saccular folds. Even this lumen is modified greatly by the tone of the musculature.

The passage of contents further is influenced by various structures along the bowel's course. The ileocecal sphincter or valve largely prevents the passage of material into the cecum when that segment is full; the valve is capable of preventing the passage of enema fluids into the ileum, though commonly it does so only partly.

The ceco-colic sphincter is a relatively constricted point between cecum and colon, due to the specially deep haustrum previously mentioned, which regulates the escape of cecal contents into the colon. This may be a factor in ileo-cecal stasis.

The colon's hepatic and splenic flexures are important divisional points.

The rectosigmoid's non-striated muscle-band narrows the junction of these portions and is located at a point where considerable angulation may take place, angulation which tends to slow the fecal stream.

The anal sphincters, internal and external, close the highly important terminus.

The mucosal folds and the *muscularis mucosae* form an active membrane with changing contours which must be regarded seriously when interpreting roentgenological silhouettes.

The position of the colon varies widely from the text-book standards of past generations. Thus, the cecum is in the iliac fossa in 85-90 per cent. of the

population and the lowest point of the transverse colon lies 3 to 4 inches below the inter-iliac line in about 40 per cent. of healthy college students. The hepatic and splenic flexures vary in position to an equally high degree and their positions (relative to each other in height) vary greatly. Today, functional efficiency assumes far greater significance than does anatomic position; in the great majority of patients the low and even the "pelvic" positions of these viscera usually bear no associated important functional relationships. Indeed, functional disturbances may occur when the viscera lie in the "text-book", presumably "normal" position. In general then the position of the viscera is not a factor indicative of function.

### COMPARATIVE ANATOMY

The human digestive tract is a compromise between those of the herbivorous and the carnivorous groups of animals; it has more of the characteristics of the carnivores as to length and more of the herbivores in respect to the cecum and the extent of sacculatation, although these features are far less developed than they are in true herbivores. The cecum and the sacculatation were developed for the long retention and thorough digestion and absorption of the celluloses. The herbivorous gut is 25 to 100 times the animal's body length, the carnivorous, 4 to 8 times and the human not over 8 or 9 times; in many instances less. These facts have real significance in the selection of the diet and the treatment of constipation.

### PHYSIOLOGY

The food which has been digested in the stomach and the upper segments of the small intestine, together with the water derived from the food and drink and such as is added in transit, normally arrive at the cecum in a soft, mixed, fluid state in from two to four hours; usually the mass has left the ileum in from four to six and one-half hours.

The gastrocolic reflex which is initiated by the ingestion of food and at times by the smell, sight or thought of it, results in the discharge of the ileal contents into the cecum.

The residue remains in the cecum and the ascending colon for the greater part of the time prior to defecation. Although most of a given "shipment" of food will be evacuated at one defecation, Alvarez has shown, by his experiments with beads, that a small part (about 15%) goes through quickly; the bulk, 50%, is passed on the second day; approximately four days are required to pass 75% of the mass. In Alvarez' studies, some individuals passed 85% in the first twenty-four hours and yet in some, nine days were required to evacuate 50-60%. Those subjects who passed most of the beads in twenty-four to forty-eight hours had accompanying soft, frothy, foul, incompletely digested food residues. The slower the passage the more formed and well digested were the stools. Probably we are correct in expecting food residues normally to pass through the alimentary tract in forty-eight to seventy-two hours and not faster. The normal stool probably is a cylindroid which shows neither fragmentation nor haustral markings, whose latter part is soft and tapering. It causes no pain or discomfort when passed.

In the colon, and particularly in the cecum and the ascending segment, churning of the mass occurs; and during this process the body retrieves the water. When the hepatic flexure is reached, the consistency of the mass has become definitely firmer. In the meantime, the cellulose has been subjected to bacterial action; it is claimed that this change permits considerable of it to be absorbed. End products of protein, fat and carbohydrate digestion are absorbed in appreciable amounts.

The material coming from the ileum seems to be pushed forward through the cecum and the ascending colon without noticeable peristaltic waves; it finally passes the hepatic flexure. In the transverse colon mass movements appear periodically; the haustrations in the transverse colon suddenly disappear, the fecal material agglomerates to form a cylindroid about 6 inches (15 cm.) long; then suddenly a contraction wave develops and the mass is driven beyond the splenic flexure into the descending colon, or perhaps as far as the recto-sigmoid. This type of activity usually occurs five or six times daily.

In the rectum, the fecal mass arouses the rectal reflex or the "call to defecation". When this is responded to, the abdominal and recto-sigmoidal muscles become active, ably seconded by the levatores ani; the anal sphincters then relax and the fecal mass is expelled.

Frequently the entire mass as far back as the splenic flexure is evacuated at one defecation. Sometimes a shorter mass, that occupying the sigmoid and rectum only, is passed. Occasionally an even larger stool is produced.

The normal person usually passes several small or one large stool daily. When a very large stool is passed, it is noted that there may follow no call to defecation for two or three days or until a period when the colon again is sufficiently filled to arouse the defecation reflex.

Further important facts are those which Alvarez has disclosed in his "gradient theory" of the mechanics of the digestive tract. A gradient is a "state of affairs" in which there is a graduated change of some given attribute over a definite time or space. Thus a glass rod heated at one end has a gradient of temperature within the two ends. Alvarez has shown definite gradients in the mechanisms of movement in the esophagus, stomach, small intestines and colon. For example, in the small intestine he has demonstrated that there exists a higher rate of rhythmic contraction in the duodenum than in the terminal portion of the ileum. There is a gradual fall in the rhythmic rate as one proceeds from the jejunum to the ileum. Similarly, studies of muscle tonus, metabolic rate and irritability show that such are more marked at the duodenum than at any point caudad. As Alvarez expresses it "the rate of rhythmic contraction continues to vary inversely as the distance from the pylorus". He further says, "the direction of transport of material in a tubular organ depends upon the gradients of rhythmicity, tone and irritability". And again "the permanence of the gradient in the gut is to be expected". He illustrates the fundamental nature of the gradient by citing an experiment with dogs in which experiment when sections of the small intestine had

been cut free, they were turned end for end and in such abnormal relationship were anastomosed. Regular healing occurred. When roughage was eliminated from their diets, the dogs were kept alive for months. Finally, they died, because intestinal obstruction occurred at the proximal anastomosis; such obstructions were caused by bits of straw, bone, wood, etc. It was shown that the original direction of peristalsis remained fixed and that only liquids could be forced through the intestinal lumen.

A second very important point is that while stimulation of the intestinal wall at any point will cause a contraction wave to travel both up and down the tube, those waves traveling up soon are obscured while those downward bound keep traveling. The gradation in rhythmicity makes this possible.

Finally, if one stimulates the intestine at a point and produces a tonic contraction then from it the waves pass cephalad and caudad and if then one starts a second tonus ring caudad to the first, the waves reaching it from above are blocked. Alvarez translates this into the law that "stimulation at any point leads to the holding back of material coming from above and the hurrying on of material already below". Call to your mind this effect as seen in the digestive tract responses in acute appendicitis, namely, early nausea and vomiting and often sudden diarrhea.

It does not appear advisable to confuse the reader at this point by injecting the problem of reverse peristalsis although even this phenomenon is in keeping with the gradient theory. This is thoroughly discussed by Alvarez in his "The Mechanics of the Digestive Tract".

Behind all which we have mentioned about the "gradients" is the power of rhythmic contraction inherent in all contractile tissues, contractions which are dependent upon rhythmically recurring chemical cycles. The rhythmic rate seems dependent upon the inherent metabolic rate of the individual tissue concerned. Thus, heat which raises the metabolic rate increases the rate of rhythmic contraction of the contractile tissue under consideration whichever that tissue may be. This fact is borne out by the intestinal musculature whether it is part of the intact body or isolated for study in the physiological laboratory.

Since completely denervated intestinal muscle still contracts rhythmically it is presumed that the "contraction wave" arises in the muscle cell itself and is conducted by it and that the function of the nerve mechanism is to coordinate or speed up movements and govern muscle tonus. This point is opposed vigorously by many physiologists.

Increase in the tension within the lumen of the bowel stimulates contraction of the muscular coat of the bowel at the distended point. This contraction increases the tension in the adjacent tissue which in turn contracts and forms part of the advancing wave which develops.

The intestinal musculo-neural apparatus has characteristic peculiarities. The contractions are more sluggish than are those of striated muscle. The tonus and hence the length of the gut constantly are changing. Several successive stimuli make it refractory. A long rest leaves the bowel very react and a

it responds promptly and explosively to a slight stimulus. This is the condition of the tract in the normal person after a night's rest and seems to explain the high efficiency of the mechanism in bringing on a bowel movement immediately after breakfast. Another characteristic is the bowel's ability to maintain a firm and lasting contraction without fatigue, a condition seen especially in the colon.

Direct, constant irritation causes spasmodic contraction; thus, an ulcer near the cardia, pylorus, ileocecal valve or the anus may cause localized spasm. Carcinomata, because of their tendency to produce degenerative changes in the muscular tissue, do not stimulate powerful contractions of the muscles, hence very often they give rise to no symptoms until mechanically they produce obstruction. The sphincters being more irritable than is the adjacent gut (since they are compact collections of muscular tissue) respond, when the gut, generally, does not.

In the limited space allowed we must be content to point out that emotional states cause digestive tract atony or persistent spasm and hence play a very important part in causing constipation. The preceding speaker has covered this point most satisfactorily. The nerve pathways affecting the colon are so poorly understood that it is best to omit them from this discussion.

The colon does not show a rhythmic rate approaching that of the small intestine, and its irritability is considerably less. The blood supply to tissues roughly parallels their metabolic rate. In illustration of this statement, it is interesting to observe that the vascular network in the mesentery becomes less abundant as we pass from the jejunum to the colon. The colon has the least volume of blood supply of the entire alimentary tract, so limited in fact that surgical procedures are handicapped as a result.

Characteristic of the muscle of the colon is its sluggishness, its relatively slow rate of contraction, its pronounced tonus-waves and its tolerance of distension. It seems designed for holding material without vigorous peristalsis for hours. The descending colon and the sigmoid probably are more sensitive than is the remainder of the colon. At autopsy they usually are found empty. The irritability of the sigmoid probably keeps the fecal mass from "packing" against the sphincter and except at such times when the pressure from above is unusually great, as for example after a meal.

Apparently a filled cecum stops the opening of the ileocecal valve. The effect of direct stimulation of the cecal mucosa through a cecostomy wound, by acid, an electrode or by pinching, tends to retard material coming down from above.

#### PATHOLOGICAL PHYSIOLOGY

Thus far, the normal physiology alone has been discussed with the exception that the spasmodic contraction of the sphincters caused by the irritation of an ulcer was noted. With this information in mind we now shall present some situations which are known to occur with constipation.

In constipation, overactivity of the colon may occur; this may take the form of rapid reabsorption of water

with resultant drying and concentration of the feces; or the more correct conception of the situation may be that there is delay in the passage of the mass through the colon which allows a longer time for dehydration. In any case, the colon's contents increase in consistency as they pass from cecum to rectum so that even at the hepatic flexure, rounded masses already may have formed; if that takes place no churning of material is possible and the individual masses are pushed onward into the rectum like cars on a track.

A condition frequently associated with constipation and, at times probably responsible for it or aggravating its degree, is distension or flatulence.

There are three main sources of gas in the digestive tract: "swallowed" air, gas derived from food by fermentation or putrefaction and gas which is liberated from the blood stream.

Air may be swallowed as such or trapped in food or drink. Most swallowed air never reaches the stomach; if it does usually it is belched promptly. With cardio-spasm and postoperatively appreciable amounts of air may be retained and may be carried into the intestinal tract to the colon. Such an happening formerly, but erroneously, was given much weight because it was not appreciated that true colonic flatus contains much nitrogen. Swallowed air has slight significance compared to true flatulence.

Fermentation particularly, and putrefaction to a far less degree, may account for important amounts of gas. In the herbivora, fermentation is the chief and a very large source of intestinal gas, but in man usually it is not. Hyperchlorhydria, by causing marked softening of the cellulose in the diet and permitting more fermentation may account for considerable gas production. Stagnation in the cecum may be favorable to added fermentation but this very stagnation provides more time for passage of gas per rectum or for absorption in the blood. The relative importance of swallowed air and gas from fermentation as against blood-derived gas seems changed in the postoperative states and in ill persons confined to bed.

The chief source of gas usually is the blood. Without going into the technicalities of the laws governing gas exchange between tissues and blood, on the one hand, and blood and the pulmonary air on the other, suffice it to say that the same laws apply in gas exchange between the blood stream and the intestinal lumen. It is certain that active exchange of gases occurs between those in the blood and those in the intestine. The normal exchange leaves very little gas residue in the intestine after the usual amount of flatus is discharged. The gases present are exchanged at rates and in the directions which the laws concerning gas pressure determine. Thus, the diffusion constants for the gases, their ability to combine chemically with hemoglobin or to dissolve in the plasma and the relative tensions of the gases present in the intestine, the tissues, the blood and the surrounding air, all play a part in the process. Hydrogen disulphide, oxygen and carbon dioxide readily are removed from the colon; hydrogen and methane may be absorbed but while nitrogen, with which the blood and tissues are saturated, easily is discharged into the intestine it is absorbed into the blood and carried away with difficulty. This physico-chemical phenomenon and not

swallowed air probably in most instances explains the high nitrogen content of intestinal flatus.

In certain conditions, the preponderance of exchange being from the blood into the colon leads to distension of the gut. It is important that one appreciates this possibility, for distension thus derived may cause or aggravate constipation. It is evident that the management of distension requires a clear understanding of the mechanism of its production.

Hence, flatulence may occur if:

1. More than the normal volume of air is swallowed.
2. The intestinal stream is delayed (by psychic or nervous causes or by constipation).
3. Carbohydrate digestion is slow or incomplete and colonic fermentation thus has opportunity to develop.
4. Absorption of gas from the bowel into the blood is diminished due to congested mucosae, atonic gut or diminished intra-abdominal pressure.
5. Circulation is interfered with when mesenteric circulation is obstructed, especially on the venous side; the gas exchange is positive for the intestine; cardiac crises; paralytic ileus.
6. The gas carrying power of the blood is diminished (probably not significant).
7. Escape of gases in the lungs is diminished as in pneumonia.

Careful consideration of all these factors is necessary when serious bowel distension threatens or exists; the significant causative factors should be prevented or diverted so as to reduce distension. Thus, changes in the diet, measures to combat intestinal stasis or to improve the circulation, treatment of disturbed respiratory situations and the combinations of these demand attention. Whenever the condition can be anticipated, measures for prevention will prove more valuable than will measures for relief. Thus in the presence of chronic passive congestion, care with the diet, the proper use of digitalis, draining of embarrassing liquid from the pleural or peritoneal sacs and the judicious use of diuretics exhibited early may prevent serious complications.

In the distension of the bowel arising in pneumonia or typhoid fever, the toxic atony of the colon by reducing the pressure of the intestinal gases may be responsible for the rapid unloading into the colon of blood gases. Here measures to combat atony or to increase intra-abdominal pressure require consideration. These therapeutic problems are very clearly discussed by Alvarez.

Fifteen and more years ago when treating diabetic patients before the advent of insulin, physicians used diets containing much roughage in the form of five per cent. vegetables. Some patients returned blessing us for relieving their constipation for the first time in their lives. Others, apparently treated similarly, developed an initial constipation. Worried, nervous and sleepless patients and patients affected with arterial hypertension when temporarily placed on sedatives frequently experienced relief from constipation. Myxedematous patients had constipation relieved by thyroid extract. Patients with achlorhydria sometimes were relieved of costiveness by hydrochloric acid. Recently, we have seen some surprising results in gastrointestinal irregularities following the correction

of certain avitaminoses. All of us know of occurrences similar to these which at the time seemed unrelated to anything in particular or even contradictory of our teachings; too many of these occurrences have been dismissed from our minds as inexplicable, insignificant or incorrect. If we have been wise enough to record them we may have profitted later when we realized their significance. Now let us consider briefly certain of these matters concerned with constipation and let us determine if possible how the physiological facts which we have reviewed explain the occurrences and clarify the course of the treatment by which the constipation may be corrected or relieved.

#### (1) DEFECACTION REFLEX

A very large portion of constipated persons are such, at least in part, because of lack of response to the urge for defecation. Sheer laziness, prudery, the demands of occupation, disgusting or ill suited toilet facilities are among the reasons why this situation is possible. When the "call" is not answered the sensitivity to the defecation stimulus tends to become weak and may disappear if constantly there is disregard of the natural sequences.

A very important sub-group is that in which there is irritation or inflammation of the ano-rectal region which renders defecation difficult or painful. Such conditions are fistula, fissure, ulceration, painful hemorrhoids, etc. Here, however, the element of sphincter-spasm enters accompanied by secondary factors which take such patients out of the class of those who merely ignore the normal defecation reflex. Furthermore, the local pathology may inhibit the complete development of the reflex. Hard, dehydrated, fragmented, fecal material may traumatize the anal region and establish sphincter-spasm.

Inflammation of nearby organs (prostate, uterus etc.,) similarly may cause constipation reflexly by holding the feces above the point where the defecation reflex is initiated.

Finally there is the group (tabes dorsalis) where the nervous mechanism itself is injured. This is especially serious when the sensory pathways are not functioning.

#### (2) DIETARY FACTORS

Sufficient tension must be developed in the rectum to set up the defecation reflex; insufficient food of itself may provide a deficient residue and no stimulation may occur. Infrequent eating may do the same and cause the reflex to occur at such widely separated times that the colon's function is weakened. The so-called "greedy colon" may absorb food and water so completely that not enough residue remains. Obstruction to the entrance of sufficient residue into the colon may occur when there is narrowing of the ileocecal valve or obstruction due to organic lesions or spasms located higher up, as in the esophagus, at the cardia or the pylorus. Pain and vomiting, of several origins, may inhibit the taking of food or cause its loss after ingestion and hence give rise to little residue in the colon. Deficient water intake may cause such a degree of inspissation of the feces that they become poorly effective stimulators of the defecation reflex or they cause local irritation which induces spasm and, secondarily, constipation. In diabetes, mellitus and

insipidus, in hyperthyroidism and in fevers so much ingested water is diverted from the bowel through the kidneys, skin or lungs that constipation may follow.

### (3) LAXATIVES, CATHARTICS AND PURGATIVES

Strictly speaking these have no separate place in the classification which this article follows but their wide use in constipation emphatically requires attention. By causing irritation and inflammation, by abstracting water and by reducing residue they cause spasm, alter secretions and reduce the fecal contents so much that no normal defecation reflex can arise. Thus they themselves may cause constipation. After the alimentary tract has been purged only harm can be done when more catharsis is sought within a period of 24 or even 48 hours. Time should be given for a sufficient residue to collect.

### (4) EXERCISE

The sedentary life leads to weak skeletal muscles. When the abdominal muscles are weak and of poor tone, and posture is incorrect, intra-abdominal pressure falls and this favors constipation. Weak muscles also render defecation difficult from lack of expelling power. Modern conveniences have not reduced the problems of constipation. The blessings and comforts of the modern toilet are outweighed by the ease of living which the elevator, washing machine, vacuum cleaner and automobile have brought to us. We have not learned to make up in pleasurable bodily exercise what we lost in unpleasant work. On the other hand muscular athletes often are constipated. Yet some persons with flabby muscles, sagging, protruberant abdomens and intestinal tracts in very low positions show no evidence of trouble. When change from activity to non-activity quickly is followed by constipation, as when one changes to a sedentary occupation or is forced by some circumstance to stay in bed, the significance of the inactivity seems clear. Departure from accustomed physical activity is a factor in constipation.

### (5) OBSTRUCTION

Bands and adhesions may kink and constrict portions of the colon. This constriction occurs most frequently in the region of the terminal ileum, the cecum, along the ascending colon and at the hepatic and splenic flexures. Right sided stasis is a well recognized result. Similar processes may occur at other points but are less common although a special and well appreciated kind of obstruction is due to malformations at the sharply-angled, pelvi-rectal junction.

Obstruction rarely arises from cicatricial lesions in the gut wall, such as healed tuberculous ulcers. Lymphogranuloma inguinale of the anus is an exception. Carcinoma commonly gives no striking evidence of its presence until there is nearly complete stenosis; this hardly comes within the scope of this paper.

### (6) STASIS

Many conditions are grouped under this head but all have the common effect of causing stagnation and delay of the fecal stream. When such occur, extraction of water rapidly takes place leaving hard fecal masses which irritate and add to the factors originally causing stasis.

Emotional states are fundamental causes of stasis. Irritating food residues, lead, tobacco, and caffeine, organic disease of the lumbar cord and irritated or inflamed mucous membrane however caused may be responsible for the condition.

### (7) SPASTIC CONSTIPATION

The old classification of constipation recognized "atonic" and "hypertonic" or "spastic" types. There is little or no supporting evidence for atonic constipation. In the spastic type, the peristaltic contractions are persistent and usually are brought on by some irritating factor such as those above mentioned. Great care in reaching a diagnosis must be used to establish the constancy of spasticity. Usually the spastic area is limited in extent. In his valuable book, "Functional Disorders of the Large Intestine", Buckstein outlines several types. He discusses "proctogenic" constipation due to spasm of the sigmoid, rectum and anal sphincters; ileal stasis due to cecal stasis and spasm of the ileocecal sphincter; colonic stasis, diffuse in distribution or localized to the cecum and ascending colon, sometimes other areas, with spasm of the distal colon; ceco-colic stasis with spasm about the hepatic flexure or any point from there onward to the splenic flexure; stasis in the transverse colon, fragmented feces beyond the splenic flexure and functional or organic obstruction at the splenic flexure accompanied by marked spasticity of the descending colon. Note in each instance that the stasis is proximal or cephalad to the point of spasm. This last type of stasis deserves comment in that there may be sharp angulation of the splenic flexure as a consequence of adhesions or gaseous distension, conditions which cause partial occlusion. This is accompanied by upward displacement of the diaphragm and the heart with resulting, annoying, cardiac oppression; rapid and small or an irregular pulse, with or without colic and acutely distressing gastro-intestinal crises. An "air lock" intensifies the situation. A similar situation may arise at the hepatic flexure.

A common form, namely stasis limited to the rectum and sigmoid has been named "dyschesia". Apparently it arises from neglected defecation reflex with loss of sensitivity, over distension of the rectum, impairment of the rectal musculature and reduction or loss of the power of expulsion. Large fecal masses accumulate, become inspissated, and cause catarrhal inflammation. This engorgement of the bowel aggravates the situation. The colonic contents actually may have to be dug out from below with a spoon or curette.

The increase in the tonus of the sphincter may be but part of the general tenseness of all of the voluntary muscles as exhibited by tired, highly nervous, psychically unstable persons.

### TREATMENT

The formation of a natural habit of bowel emptying most emphatically should begin in infancy. Just after breakfast, physiologically, is the ideal time for defecation. Perhaps we should say "after the meal which closes the longest fast period of the day". The attempt to expel a stool should be made then even though there is no "call". Voluntary action, as by forcible contraction of the abdominal muscles, may push the feces down into the rectum and thus start the reflex. "Calls" should be responded to at whatever time in the day they may come. Of great importance

as a prophylaxis against constipation is the rising of individuals at an hour sufficiently early and the opening of schools and offices at an hour sufficiently late that all persons may have opportunity to have stools after breakfast and before the day's work starts.

The diet should be fitted to the problem. For spasm in general, a smooth diet relatively free from roughage and cellulose should be exhibited. Remember that muscle spasm is only one factor in the constitutional make up of a high tension individual. Rest, relaxation, elimination or reduction of responsibilities, the development of a more leisurely spirit and sometimes, medicinally, the administration of sedatives are measures of importance.

If the patient is of the kind who responds to all digestive disturbances by the elimination from his diet of first one food and then another, the problem of lack of food volume, calories, vitamins and roughage may arise. My own experience has taught me that this occurs with considerably greater frequency than I at first supposed. Experience with severer grades of avitaminosis has taught me to recognize the milder forms of vitamin lack. Frequently, such patients resist the replacement in their diet of the vitamin-rich foods because of the distress they arouse. In such circumstances the concentrated preparations of vitamins are of a value which outweighs their great cost.

Thorough food mastication should be insisted upon. Diets high in carbohydrates, especially glucose, should be used guardedly where bowel distension complicates the constipation. Milk often causes similar trouble. In certain patients, when enteroptosis is associated with constipation, hyperalimentation may be called for but in these subjects where ptosis actually causes deficient food mixing and food stasis, periods of complete rest, physical and mental, and the application of abdominal supports, properly fitted with pads, while in the prone position, are valuable adjuncts to dietotherapy. When hyperchlorhydria is present a high fat diet tends to alleviate the condition. In stasis, especially when of the right colon, cellulose should be limited in the diet. Abundant water should be taken regularly unless there are specific, important contraindications.

Bran or bran-containing, so-called "health foods", should be used cautiously. Death has followed its use due to impaction and subsequent rupture of the intestine. These occurrences are not easily detected in the making, however in elderly people the terminal symptoms may appear acutely and create puzzling diagnostic problems.

In the hands of many atropine is believed useful in managing spastic constipation. It must be given in full physiological dose for the individual. The sedatives, bromide and chloral, frequently are considerable aids in securing bowel relaxation in the tense individual. Some clinicians believe that thyroid extract is valuable in treating the constipation of myxedema. The constipation occasionally noted with Grave's disease may become less pronounced after partial thyroidectomy.

Mineral oil or agar, separately or together, are of very real help in starting patients back toward normal functioning. Especially are they valuable when right colon stasis and inspissation of the feces are factors. The action of mineral oil in preventing the absorption of the fat soluble vitamins must be circumvented.

Enemata of plain tap water or physiological saline solution used simply to arouse the defecation reflex may help in the re-education of the bowel. They should not be used constantly or over long periods. Colon irrigations and enemata while of real value undoubtedly are abused to a serious degree; it is to be hoped that present conditions have awakened many patients to the fact that they are better off without long courses of these treatments unless the colon lavage is given under competent medical guidance.

Local anal and rectal irritation should be treated carefully. Often the aid of a proctologist is invaluable in relieving such lesions and shortening the period of illness. If low rectal and anal affections are present the feces should be kept soft and non-irritating. In selected minor rectal and sphincter lesions, I have found small enemata of tannic acid solution or a strong infusion of tea leaves great help particularly when such enemata are at a temperature of 100° F. and are instilled slowly with the patient lying on his back.

Irritating conditions of systemic or constitutional origin as causes of colon spasm should receive appropriate local or general treatment as indicated. At times surgery may be called for, but the variety of conditions demanding such cannot be discussed here.

Gymnastic and outdoor exercises, hydrotherapy and massage all have their places in treatment of certain patients. However it is very unlikely that any so-called "manipulations" will move fecal masses along the colon. Such was the abdominal massage of olden days carried out with the aid of a heavy iron ball.

Finally, when kinking, obstruction, diverticula, etc., are the causes of constipation, surgery may be of the greatest service. It should be decided upon only after very careful observations and carried out with great judgment and skill. Too many instances of constipation and obstruction have followed surgical operations. The surgery requisite for the correction of some of these conditions entails a very high degree of technical skill and judgment.

It must be evident from this review that constipation not only is an important subject in itself but that it is the presenting syndrome of a number of medical conditions which themselves must be attacked if success is to follow treatment. A few such conditions may be listed: drug addiction, pituitary conditions of several types, diabetes mellitus, obesity, malnutrition, achlorhydria, polyneuritis, scurvy, pellagra, gout, tuberculosis, pneumonia and other fevers, concussion of the brain, epidemic encephalitis, tabes dorsalis, arterial sclerosis and peptic ulcer. Successfully to deal with the constipation syndrome in many cases requires most carefully taken and searching histories, exhaustive physical examinations, and general laboratory, metabolic and roentgenologic studies. Constipation presents for its etiologic solution problems demanding the highest professional skill; in its treatment great ingenuity, patience and medical and nutritional experience are called for. In its surgical management all fields of operative procedure may have to be entered. In certain instances, advances in neuro-surgery offer much promise but until much more is known of the function of the spinal nerves and the ganglia restraint should be the rule in this field.

# The Weltmann Test in Diseases of the Liver<sup>3</sup>

By

MANFRED KRAEMER, M.D.  
NEWARK, NEW JERSEY

THE difficulty in making a positive clinical differentiation between a parenchymatous (catarrhal or cirrhotic) and an obstructive jaundice is generally recognized. The many tests of liver function (1, 2, 3, 4, 5, 6) now in vogue suggest that likewise there is no absolute laboratory procedure which can tell us whether, in a given case of jaundice, we are dealing with a parenchymatous or an obstructive process.

Many authors (7, 8, 9) find the galactose tolerance test of Bauer most valuable in making a differentiation, but others, notably Banks, Sprague, and Snell (10) feel that its usefulness is very much limited. In private practice, and when performed promptly after the appearance of jaundice, our experience with Bauer's test has been favorable. However, in the wards of a public hospital the performance of the test is too time-consuming and expensive. Where chemicals are purchased by "bids," an impure galactose may be substituted for the more costly C.P. product. This use of impure galactose makes results very difficult to evaluate. The galactose test takes five hours for its completion and requires the collection of all urine passed within that time. In wards inadequately staffed, patients unwittingly void specimens into urinals which are emptied into a toilet instead of being saved. In patients with associated prostatic disease, diabetes, or kidney disfunction, it is almost impossible to get an accurate idea of galactose utilization.

The above is my *apologia* for the discussion of a test for liver disease which may prove as valuable as the galactose tolerance test but which is both simpler and easier to perform and which can be carried out at a negligible cost.

Oskar Weltmann, a clinician and physiological chemist, who had for some time been studying liver disease (11, 12, 13, 14, 15) published in February, 1930, (16) the result of some researches on the effect of certain pathological processes on the coagulability of the blood serum. By October, 1930, (17) he had applied these changes in blood serum coagulability to a test for the differential diagnosis between obstructive and parenchymatous states of the liver. He called his test the 'Serums Koagulations Band' and abbreviated this title to 'K.B.' This test was later elaborated upon by Weltmann (18). European writers have used the test not only in differentiating hepatic diseases but also as an aid to the diagnosis of a great variety of disease conditions. No reports have appeared in the English literature. In this paper, we shall confine ourselves to a description of the test, reports of the

literature, and a preliminary report of our findings with this test in hepatic diseases.

## DESCRIPTION OF THE TEST

If blood serum be diluted with distilled water and boiled, the coagulability of the serum depends upon the presence of a certain minimal quantity of electrolytes. Thus, the protein in a 1:50 dilution of blood serum in distilled water does not coagulate by boiling, but coagulation immediately appears if a small amount of sodium chloride, calcium chloride or barium chloride is added to the boiling dilution.

Weltmann determined that, in a boiling 1:50 dilution of normal blood serum, the lowest concentration of calcium chloride solution in which coagulation of the serum protein takes place is from .03 to .04 per cent. That is, if 0.1 c.c. of normal blood serum is added to 5 c.c. of .02% calcium chloride solution and boiled, no coagulation takes place. However, if 0.1 c.c. of normal blood serum is added to 5 c.c. of .04% calcium chloride solution and boiled, the serum protein coagulates.

It was found that inflammatory and exudative processes (pneumonia) changed the blood serum so that the protein was coagulated in only the more highly concentrated solutions of boiled calcium chloride, as .08%. On the other hand, disease of the parenchyma of the liver, cardiac decompensation with stasis, and fibrous forms of tuberculosis so changed the blood serum that the protein was coagulated in much lower dilutions of boiled calcium chloride, *e.g.* .02%. These observations have been confirmed by a number of investigators to whom I shall refer later.

On the basis of these findings the Weltmann serum coagulation test was devised. The technic follows:

## TECHNIC

In stock are kept eleven large (500 c.c.) bottles of the following solutions of anhydrous calcium chloride: 0.1%, .09%, .08%, .07%, .06%, .05%, .04%, .035%, .03%, .02%, .01%. These bottles are numbered from 1 to 11. Number 1 corresponds to 0.1% and number 11 to .01% dilution of calcium chloride.

Eleven test tubes are placed in a rack. To each tube 5 c.c. of a different one of the dilutions of calcium chloride is added. A different 5 c.c. volumetric pipette is used for each bottle. The tubes are numbered 1 to 11 to correspond to the stock bottles. Then to each test tube 0.1 c.c. of the serum to be tested is added, this serum having been collected by the usual method as for a Wasserman test. The tubes are shaken and then placed in a boiling water bath for fifteen minutes. A large water bath is used so that the entire test tube rack may be placed into the bath and removed without disturbing the position of the tubes. After fifteen minutes boiling, the tubes are removed from the water bath and the weakest solution of calcium chloride in

<sup>3</sup>From the Medical Service of Dr. Frederick Alling, Newark City Hospital.  
Submitted December 3, 1934.

which coagulation has taken place is determined. In the reading, lumping of the protein not turbidity is considered. The number of the tube containing the weakest solution in which lumping (coagulation) takes place determines the length of the coagulation band (C.B.).

In normal serum, the coagulation band has almost a constant length reaching to the 7th or 8th tube, corresponding to a calcium chloride dilution of .04 to .035%. In certain diseases the coagulation is either shortened (coagulation in less than 7 tubes) or lengthened (coagulation in more than 8 tubes). A short C.B. or no coagulation at all is observed in pneumonia, acute rheumatic fever, and in other infectious or exudative processes. A lengthened coagulation band occurs in cirrhosis of the liver, in all parenchymatous affections of the liver, and in all fibrous processes.

The method has its limitations in the cases in which exudative-inflammatory and fibrous processes are associated. In these cases a normal C.B. may result from the antagonistic effect of the two processes. Thus extensive destruction of liver tissue by fibrosis following obstructions by a neoplasm may lead to a lengthening of the band. (cf. Table, Case 24)

#### REVIEW OF LITERATURE

As previously mentioned, the test has been found useful in the diagnosis and prognosis of several diseases. The value of the test in the differentiation of exudative and fibrous tuberculosis was first shown by Weltmann (16, 17) and has been confirmed by others. (19, 20, 21, 22, 23) Rohacova and Weicherz (21) and others (19, 22) found the C.B. of greater prognostic value in tuberculosis than the sedimentation rate of erythrocytes. Writers who have employed the test have found it of diagnostic and prognostic value in pleurisy (24), gynecological conditions (25, 26), and pneumonia (18). Klaston (27) has described changes in the C.B. in pregnancy associated with such complications as pyelitis and mastitis or alterations in the liver. Kretz (28) studied the C.B. of 420 patients before and after various abdominal operations and noted a shortening of the band post-operatively with a return to normal quite rapidly. Such complications of the recuperative processes as abscesses, and thrombophlebitis caused continued shortening of the band.

The value of the coagulation band in the differential diagnosis of liver diseases has been established by many writers (16, 17, 18, 29, 30, 19, 31, 32, 33).

We have made no study as to the reasons for the phenomena observed in this test. Some function of the liver must be responsible for the changes found, because in other diseases in which hepatic function may be involved, as in pernicious anemia (cf. Table, Cases 19, 20 and 21), diabetes melitus, and chronic alcoholism the effect is the same as that observed in cirrhosis (33). Weltmann (18) and others (34) showed the reaction depends upon a change in the serum albumen, and not in a change in the serum calcium as suggested by Kaiser (20). Although the cause of the coagulation band is unsolved, its regular and constant changes in certain diseases and its simple technic may make it a useful diagnostic means, especially in the field of liver pathology.

#### COMMENT

Our results, which are shown in the accompanying table, have in the main agreed with those of the

TABLE I  
*The Coagulation Band (C.B.) In 25 Cases of Liver Disease.*

| Case | Age | Sex | Ict. Index | C.B. | Diagnosis                                                                           |
|------|-----|-----|------------|------|-------------------------------------------------------------------------------------|
| 1.   | 51  | F.  | 22.5       | 8    | Stone in comon duct. (Laparotomy)                                                   |

| 12.  | 26  | M.  | 80         | 10   | Parenchymatous jaundice.                                                            |
| 13.  | 59  | F.  | 150        | 10   | Parenchymatous jaundice.                                                            |
| 14.  | 57  | F.  | 30         | 10   | Parenchymatous jaundice.                                                            |
| 15.  | 66  | M.  | 30         | 10   | Parenchymatous jaundice.                                                            |
| 16.  | 63  | F.  | 15         | 10   | Cholangitis. (Laparotomy)                                                           |
| 17.  | 52  | F.  | 31         | 10   | Cholangitis. (Laparotomy)                                                           |
| 18.  | 39  | M.  |            | 11   | Cholangitis. Cholecystitis. (Laparotomy)                                            |
| 19.  | 30  | M.  | 15         | 10   | Pernicious anemia.                                                                  |
| 20.  | 30  | M.  |            | 10   | Pernicious anemia.                                                                  |
| 21.  | 53  | M.  |            | 10   | Pernicious anemia.                                                                  |
| 22.  | 52  | M.  | 48         | 9    | Primary cancer of bile ducts. (Laparotomy)                                          |
| 23.  | 36  | M.  | 15         | 9    | Miliary tuberculosis.                                                               |
| 24.  | 58  | M.  | 75         | 10   | Cancer of head of pancreas, with obstruction of common duct of long duration.       |
| 25.  | 47  | M.  | 50         | 10   | Primary cancer of liver. (Laparotomy)                                               |

writers to whom we have referred. The test should prove valuable chiefly in determining whether or not a given case of jaundice is of an obstructive or of a parenchymatous nature. The cases of pernicious anemia and the case of familial hemolytic icterus showed results similar to those in parenchymatous jaundice, i.e. lengthening. The test does not aid in differentiating between an obstructive jaundice due to stone (Case 1) and one due to neoplasm. Case 3). In both the C.B. would be normal. In either case, however, surgical exploration is generally considered the proper procedure. Uniformly the patients with simple parenchymatous icterus (catarrhal jaundice) and those with cirrhosis with icterus showed lengthening of the band. Unfortunately, the number of cases of early obstructive jaundice coming to our attention have been few—only three cases in the past year. Case 24, which was diagnosed as carcinoma of the head of the pancreas showed lengthening. The obstruction, if this diagnosis was correct, (and we are not sure that it was, since the patient improved and left the hospital without a laparotomy) was of long standing and probably resulted in back-pressure on the liver with considerable parenchymatous damage, (as occurred in Case 9) which would have accounted for the lengthening of the band.

Our material has been too limited to enable us to evaluate this test properly. We present this preliminary report in the hope that the use of this test will be investigated by others. We believe that further use and study of the test in a large number of cases by critical investigators may elucidate a number of clinical problems.

#### ACKNOWLEDGMENT

I wish to acknowledge the assistance rendered by Dr. George Hewson.

## ABSTRACTS

G. M. DACK AND ELIZABETH PETRAN, Chicago, Ill.

*Experimental Dysentery. Pages 1-6, 1934, Vol. 55, No. 1.*

A study was made of bacterial activity in two isolated segments of large intestine of monkeys into which dysentery bacilli were injected. This gave opportunity to determine bacterial changes in the absence of micro-organisms carried by the fecal stream. The opportunity for these dysentery bacilli to establish themselves may be quite variable. Freshly isolated virulent strains of these organisms, inoculated into isolated loops of colon in adult monkeys, produced an infection in the loops, which resulted in a profuse bloody mucous discharge. Marked systemic reaction accompanied the infection in the loops of intestine; this was characterized by pallor, loss of appetite, leukopenia, loss of weight, and prostration. The acute symptoms appeared within forty-eight hours and lasted three to four days. Within a week the discharge from the fistulas had ceased and systemic symptoms had disappeared. The severe systemic reactions may have been the result of absorption of toxins. Agglutinins for *Bacterium dysenteriae* (Flexner) were demonstrated in the serum of the animals. No evidence of infection was apparent in that portion of the colon through which the fecal stream passed.

However, severe symptoms of dysentery developed in two large adult monkeys which were fed the same strains of organisms.

It would seem, then that the fecal strain is not essential for the dysentery bacillus to establish itself and produce infection.

J. Arnold Bargaen, Rochester, Minn.

SCHIFF, LEON, AND SENIOR, FANNY A.

*Jaundice, With Particular Reference to Galactose Tolerance, Jour. of the A. M. A., 103:1924, Dec. 22, 1934.*

The authors studied 100 cases of jaundice with particular reference to galactose tolerance.

There were 50 cases of catarrhal jaundice. In forty-seven of these cases a positive galactose test (excretion of three grams or more) was obtained on the first examination. In two additional cases positive tests were obtained on second examination.

In fifteen cases of toxic hepatitis the test was positive in fourteen.

In a group of twenty cases of obstructive jaundice due to stone in common duct, cholangitis, pancreatitis, pancreatic carcinoma, and pancreatic cyst, the galactose test was negative in all of these cases.

In ten cases of cirrhosis of the liver the galactose test was negative in six cases and positive in four.

In carcinoma of the liver, the galactose test was negative in four out of five cases.

In the above study serum bilirubin determination and bromsulphalein retention tests were made. From comparison of these studies the authors find that the galactose tolerance bears no relationship to the degree or duration of the jaundice or to the amount of bromsulphalein retention.

Discussions by Dr. Harry Shay and Dr. F. C. Mann follow.

Francis D. Murphy, M.D., Milwaukee, Wis.

# Diverticula of the Duodenum and Diabetes

By

WILLIAM B. THORNING, Jr., M.D.

and

HOWARD F. ROOT, M.D.

BOSTON, MASSACHUSETTS

THE occurrence of five duodenal diverticula in a diabetic patient, previously operated upon for gall stones, raises numerous questions regarding the etiology of diverticula, their differential diagnosis, and treatment. Although often regarded as causing no symptoms, recent reports indicate that such diverticula may simulate duodenal or gastric ulcer, gall bladder or pancreatic disease. Indeed acute and chronic pancreatitis have been attributed to extension of inflammation from such diverticula. The association of duodenal diverticula and diabetes, therefore, has a special interest. The following cases illustrating the complexities arising are presented with a brief discussion of diverticulosis of the duodenum and ileum.

## HISTORY

Case I (3782), Jewish housewife, aged 66 years entered the New England Deaconess Hospital October 25, 1934, complaining of pyrosis, substernal pain and pain in either hypochondriac area coming on usually one hour after eating but frequently at night and often with nausea. Vomiting rarely occurs and she has had no hematemesis. Constipation, weakness, swelling of the upper abdomen and a loss of 22 pounds in weight during the last 5 years are recorded. Relief has been obtained frequently by induced vomiting and the use of alkalies but not by means of food.

The onset of these abdominal symptoms, although stated by the patient to have occurred about the time when she developed diabetes, December, 1923, is difficult to determine, owing to their possible confusion with symptoms related to her gall-stones. Previous hospital records show complaints of pyrosis and upper abdominal symptoms for 32 years.

Through the courtesy of Dr. George H. Stone of the Memorial Hospital, Worcester, Mass., her record from December 24, 1914, to March 13, 1918, is available and describes attacks occurring at irregular periods of chills, vomiting and marked pain in the left upper abdominal quadrant. These attacks began in 1902. At operation performed in 1915 at the Memorial Hospital, the following notes were made: "Right rectus incision, gall bladder exposed and found to be greatly thickened and adherent to surrounding structures. Gall bladder partially freed from adhesions and more fully exposed. Trocar and canula were inserted but no bile secured. Gall bladder opened and small amount of bile was drained out. Many soft stones were found and removed with curette. Common duct palpated and found to contain a mass of soft stones. Gall bladder completely freed from surrounding structures and amputated near base of cystic duct. A large amount of debris containing many small soft stones was curetted from common duct. A rubber tube was inserted in duct and two Penrose drains threaded with iodoform gauze placed in wound."

In 1918 she still complained of gas, vomiting and had had chilly sensations and fever.

Tuberculosis was suspected but no confirmatory evidence obtained.

Palpitation of the heart, dyspnea on exertion without edema of ankles and a ringing sound in left side of head were the only symptoms outside the gastro-intestinal tract at the present admission.

## PHYSICAL EXAMINATION

Weight 101 pounds (net), Blood Pressure 180/90.

A visible dilatation of the right carotid artery at the base of the neck one and one-half centimeters in length and breadth. Few subcrepitant rales at lung bases without dulness. The heart sounds were regular and of good quality with a systolic basal murmur which is accentuated over the aorta with the patient sitting upright. The heart was moderately enlarged, the total diameter by x-ray being 14.3 c.m., as compared with chest diameter of 23.9 c.m. and a calcified plaque was visible in the arch of the aorta. Radial arteries were tortuous and moderately sclerotic. The abdomen was mildly distended, not resistant but rather doughy without tenderness. Liver palpable two centimeters below costal margin but smooth. Extremities thin, musculature flabby, no edema, reflexes present and equal.

## LABORATORY DATA

The blood sugar values were 0.19 per cent fasting and 0.24 per cent after a meal, non-protein nitrogen 25 milligrams per 100 c.c. The first urine specimen contained 0.9 per cent sugar but thereafter was sugar free with doses of insulin ranging from 5 to 8 units. White blood count 13,700, hemoglobin 77 per cent (Sheftel) red blood count 4,800,000, differential count normal. Gastric aspiration with alcohol meal showed no free hydrochloric acid and strongly positive benzidine tests in five specimens. A little fresh blood was probably due to trauma from the tube. Electrocardiogram showed left ventricular preponderance. The S-T interval was depressed in Lead I and elevated in Lead III. The P-R interval was 0.14 seconds.

10/30/34 *Roentgen Examination of the Gastro Intestinal Tract*: The kidney outlines are obscured by fecal matter. The stomach is normal in size and position, and regular in outline. The duodenal cap is enormously dilated. Five diverticula are seen in the region of the duodenum varying in size from one and one-half c.m. to six c.m. in diameter. A diverticulum three c.m. in diameter is seen in the jejunum. The diverticula remained filled for a seven hour period. At this time the stomach is empty and the head of the column is in the rectum. In twenty-four hours there was a small quantity of barium in one of the diverticula. The barium is massed in the large intestine from the splenic flexure to the rectum. The remainder of the large intestine is empty. Diverticula of the duodenum, single diverticulum of the jejunum with delay and dilatation of the duodenal cap and hyperactivity of the colon. (Dr. I. K. Bogan) D.

In Figures 1 and 2 are shown the diverticula.

The patient became more comfortable while in bed, but pain in the epigastrium, gas and nausea have continued at home. On Dec. 18, 1934, she had gained 5 lbs. and had improved in general condition.

Case II (13253), physician, age 74 years, entered the New England Deaconess Hospital November 30, 1934. Diabetes began in June, 1934, with nocturia and later polydipsia and polyuria. The blood sugar was 0.40 per cent October 1, 1934.

His digestive symptoms first began in 1926. At this time the gall bladder and many stones were removed. He was fairly well until October, 1934, when jaundice appeared with loose clay-colored stools.

Upon admission his weight was 136 pounds, a loss of 20 pounds from his maximum weight. Jaundice was marked. A large hard nodular mass, apparently the liver filled the epigastrium. Ascites was present. The blood bilirubin was 7.5 milligrams and the blood sugar 0.19 (190 milligrams) per cent. He had taken 18 units of insulin daily.

The gastro-intestinal x-ray report follows: 11/30/34 Barium passed to the stomach without delay. Stomach normal in outline. Pylorus opened filling normal duodenal cap. The second portion of the loop emptied rather rapidly and there was a diverticulum within the loop. Examination fails to demonstrate any evidence of intrinsic disease of the esophagus, stomach or duodenum. The loop shows a diverticulum and adjacent portions of the loop empty rather rapidly. The loop is not increased in size. (Dr. Jack Spencer).

The diverticulum measured one and one-half inches in diameter and arose on the mesial surface of the descending portion of the duodenum apparently resting on the head of the duodenum.

Owing to his general condition, the apparently rapid growth of a carcinoma arising either in the pancreas or gall ducts, operation was not advised.

### DISCUSSION

The downward course of Case I over a period of five years may be attributed to several causes, cardiovascular disease, a possible gall stone in the common duct, a neoplasm and the results of the duodenal diverticula. In Case II we have no suggestion that the diverticulum is responsible for symptoms or pancreatitis. In attempting to evaluate the significance of the diverticula, their frequency without serious symptoms as well as the complications produced by them, must be borne in mind.

### INCIDENCE OF DIVERTICULOSIS

Autopsy figures indicate according to Fraser (1) that from 0.5 to 1 per cent of all individuals possess diverticula of the small intestine not including Meckel's type. The duodenum, jejunum and ileum are in the order named the most common locations. Fraser (1) also reports that of five thousand cases from one hospital only two cases of this condition were so diagnosed clinically. This discrepancy between autopsy and clinical reports is explained by the large percentage of cases which are symptom free or have mild unexplained symptoms. The incidence of diagnosis, however, is on the increase as Edwards (2) finds that by roentgenography the percentage of cases rose from 0.2 in the years 1925, 1926 and 1927 to 0.9 in 1928. At the latter date the technique of examination was changed to include roentgenograms made from various angles of exposure. Since that time the increase has maintained itself through 1931 in a total of 4,631 cases. Carlson (3) found 112 cases in the literature up to 1912 and up to 1933 found 423 of which 66 were diagnosed at operation. Their occurrence in diabetics must be rare.

Children rarely are found with the condition. Horton and Muellér (4) in 122 autopsied cases reported a

22 year old woman with diverticula as the youngest. Those found in children are usually thought to be enterogenous in origin. Her cases showed a marked preponderance in the male sex. Edwards (2) states the age incidence of formation is 35 to 40 years. In our Case I the diverticula were not discovered at operation performed in 1915, or noted in gastro-intestinal x-ray examination carried out in another hospital in 1932. If they were actually absent at those times, their formation has occurred at about the age of 65 years. The facts that they did not always fill with barium and that, in the presence of adhesions they may easily be missed at operation, together with the constancy of her symptoms for at least 32 years lead us to believe that they probably developed between the 30th and 35th year.

### CLASSIFICATION

Fraser (1) classifies diverticula of the small intestine under four headings. 1. The multiple false or acquired variety. 2. The enterogenous which are formed from islands of cells separated from the primitive gut, becoming hollow and attached to the intestine in later life. 3. The anomalous which include diverticula incidental to the drag of a tumor, adhesions often related to cholelithiasis and cholecystitis, a healing peptic ulcer with shortening the duodenum, the softening of glands, or a tumor in the intestinal wall. 4. Meckel's diverticulum. Chapman (5) introduces a separate class by excluding all cases that are not multiple.

### ETIOLOGY

The etiology of the condition has been reduced to three prominent factors by Fraser. (1) 1. Presence of greater pressure in the lumen of the intestine than is normal. One such cause is illustrated by a stricture distal to the diverticula with accompanying symptoms of long-standing rectal or vesicle tenesmus. 2. The position of the nutrient vessels. Nearly all diverticula unless very large can be shown to be adjacent to the blood vessels at their point of entry into the intestine. The blood vessels are two in number for each section of the intestine and Edwards (2) finds that when small, most diverticula are double, and with increase in size form one by fusion. Many large diverticula have a reminder of this in a dimpling of the fundus produced by the band of muscle which at first separated two sacs. In our case diverticula 1 and 2 may actually be such a single dumb-bell shaped diverticulum. Horton (4) does not find this relation to blood vessels is true in the duodenum but considers that bits of pancreatic tissue are very common in the longitudinal muscular coat serving as points of lowered resistance in the intestinal wall. 3. Defects in the longitudinal layer of muscle of the small intestine particularly along the mesenteric border. Through these defects is herniated the mucosa producing the diverticulum. This herniation takes place along the course of the artery which in itself forms a weakness in the circular muscle coat. These devorications are more prevalent in the proximal portions of the small intestine as the diameter in that area is three times that of the distal portion so that a constant amount of muscle has a greater area of distribution. This is consistent with the finding of more diverticula in the proximal portions. Butler (6) on the basis of experimental work postulates traction by unelastic arteri-

Fig. 1. Film taken 15 minutes after barium sulphate given by mouth. The course of the duodenum is marked by arrows. Diverticula 1, 2, 3 and 4 arise in the first portion of the duodenum, apparently from the upper and lower borders. Numbers 1 and 2 may in reality be a single dumb-bell-shaped diverticulum, but appeared to be two diverticula in close apposition. The extraordinary width of the first portion of the duodenum was unexplained. Diverticulum number 5 arises from mesial border of the descending portion of the duodenum, and projecting inward, apparently, together with number 2, is in close relationship with the head of the pancreas. The extraordinary redundancy of the duodenal cap is unexplained. Exposures made with patient lying down.

osclerotic vessels in addition to increased internal pressure as a factor and that the early herniations are of all four coats rather than of the mucosa alone.

### FUNCTIONAL PATHOLOGY

When the small diverticula begin they are protruding into the mesentery between its peritoneal leaves and on enlarging tend to extrude themselves carrying a covering of peritoneum from the leaf of the mesentery with them. As the evaginations reach golf ball size or larger their own weight tends to cause sagging thus kinking the neck of the sac. This occlusion accounts for the gas formation and abdominal distention which are so common. Many duodenal diverticula, however, tend to burrow in relation to the pancreas and receive no peritoneal coat. Histologically, usually only mucosa, often atrophic, and areolar tissue with or without peritoneum are seen on the well developed diverticula; there being no muscle tissue there is no power to produce colic or to empty the sac contents although it is usually liquid chyme. However, in a diverticulum of the duodenum recently removed at operation at the Deaconess Hospital, a normal muscular layer was present. The response to gravity in the position assumed by the diverticulum explains the comfort obtained from lying down. Although the duodenum is the commonest site they are usually single here; the jejunum and ileum are less frequently the site, but when so usually bear multiple sacs, sometimes into the hundreds. The symptoms vary with the location, size and number and secondary complications. Fulde (7) has demonstrated the relationship of duodenal diverticula and chronic pancreatitis. He studied 207 cases of diverticulosis of the duodenum and in 28 cases found more or less significant accompanying diseases of the pancreas. Two cases showed adhesions due to peri-diverticulitis and peri-pancreatitis. In 8 cases there were more or less out-spoken chronic pancreatitis, 5 cases went to pancreatic necrosis, 3 cases of phlegmon of duodenum. Three cases of carcinoma of the pancreas accompanied duodenal diverticulosis. Diverticula are often, according to Fulde, the starting point of chronic processes in the pancreas, owing to their frequent position in the descending duodenum

on the side adjacent to the pancreas. The reason is the opportunity for stasis and bacterial decomposition of the duodenal contents in the pouches and sometimes the inflammatory processes in the neck of the diverticulum. Two things may happen: 1. Direct extension, by way of lymph channels, of the inflammatory process. 2. Indirectly by the contents of the sac passing through Vater's papilla into gall ducts or pancreatic ducts. Catarrh of the duodenum may be so produced. Repetition of these processes may cause chronic pancreatitis. Through swelling of the papilla Wirsung's duct may be closed and an atrophy of the pancreas follow. He reports three cases showing disturbances in the external secretory function of the pancreas with fat in the stools, absence of trypsin and lipase in the duodenal contents. However, none of these cases had diabetes. Kellogg (14) in his monograph on the duodenum does not mention diabetes in connection with duodenal diverticula.

### DIAGNOSIS

Diverticulosis of the small intestine can occur without symptoms sufficiently definite to permit definite diagnosis. Fraser (1) goes so far as to say that three-fourths of the cases have no symptoms. However, in cases with multiple diverticula of the duodenum such as are here described, gastro-intestinal symptoms may well be attributed to this cause. The cases so far reported may be classified in several groups.

In one class an acute abdominal condition is presented perhaps with little or no history of previous discomfort. Cases clinically resembling perforated peptic ulcer, Flynn (8), intestinal obstruction, (6) general peritonitis, (1) and perforated gastric malignancy, Davis (9) have been described. In a third class a variety of complaints of long duration occur. In a series of 14 cases, Gibbon (10) found 10 which had a previous diagnosis of neurosis. Although there are no pathognomonic symptoms, three stand out as most frequent. 1. Marked rumbling of gas in the abdomen; 2. A soft upper abdominal distention noticed by the patient, and 3. Relief from gas and pain on lying down. In addition, periodic upper abdominal pain after meals, not usually relieved by food but alleviated by alkalies in addition to eructation, pyrosis, and borborygmus sometimes more annoying than the pain are described. Vomiting is variable, often produced voluntarily. Hematemesis and melena are rare. Constipation is most common and a definite weight loss hardly less so. Diagnosis must rest on the demonstration of diverticula by barium meal, possibly by the presence of air sacs in a flat abdominal plate. However, it is stressed by Edwards (2) that retention of barium for only an hour or two is not an adequate ex-

Fig. 2. Film taken 2 hours after barium by mouth. Diverticula 1, 2, 3 and 5 are clearly outlined but 4 is not seen.

planation for symptoms. Davis (9) presents a case with six-hour retention in a duodenal diverticulum but after removing a common duct stone the patient was relieved and continued to be so at a five year examination. In our case removal of gall-bladder and stones in the common duct gave no relief of symptoms. On the other hand, King (11) removed a duodenal diverticulum which emptied in six hours with relief, but was not followed. Many cases exhibit retention for twenty-four hours or more. Diagnosis at operation is not always easy. Fulde (7) explains the failure to find diverticula at operation as due to adhesions from peri-pancreatitis.

### DIFFERENTIAL DIAGNOSIS

The existence of diverticula having been demonstrated by roentgenogram, the practical problem becomes one of determining whether sufficient explanation of symptoms has been found, or whether other lesions are present.

The three conditions to be eliminated most commonly are ulcer of the stomach or duodenum by its absence in roentgenograms, gastric carcinoma by the same means, cholecystitis and cholelithiasis by appropriate studies. Repeated examination both by fluoroscopy and numerous plates taken from different angles may be necessary for their demonstration. Chronic pancreatitis, intestinal polyposis, and heart disease will occasionally have to be ruled out. Horton and Mueller's (4) studies indicate that 32 per cent of cases are associated with cholecystitis, the age incidence of the two being similar. It must not be thought that a stone in the common duct is ruled out by the absence of jaundice. Most observers agree that unless 6-hour retention of barium in the diverticula can be demonstrated, symptoms may not be attributed to this cause. The long duration of epigastric distress, pain, pyrosis, induced vomiting without hematemesis, absence of relief by food, but relief by change of position, characterize diverticula.

### TREATMENT

It seems reasonable to permit those cases of multiple small diverticula, without symptoms causing grave discomfort discovered accidentally by barium meal, to avoid operation. A low residue diet, avoidance of constipation and straining and removal of any known causes for intestinal delay are indicated. Those cases discovered at operation will be treated as their size, number and location indicate in the operator's judgment. Fraser (1) mentions two cases which were thought

inoperable when discovered at operation but subsequently had to undergo enterectomy in a second operation.

The group which present symptoms definitely related to the diverticula even if mild had best be operated upon, in Fraser's (1) opinion, as a spontaneous cure is impossible and practically all patients who later develop serious complications such as diverticulitis, perforation or intestinal obstruction, Abell (12) had had symptoms for a considerable period.

Barnes (13) gives the operative procedures applicable to the different situations arising as resection of the diverticula with suture, resection with inversion of the stump, inversion with or without resection, resection and suture with or without gastroenterostomy, gastroenterostomy with or without occlusion of pylorus, resection of bowel. These are serious operations, and not to be advised without careful consideration. As in our Case I, complications may be important, and the difficulty of assigning with certainty the symptoms in question to the diverticula is great.

### SUMMARY

Diverticula in the duodenum are reported in two diabetics with previous operation for gall-stones. The possibility that inflammation in or about such diverticula can by extension cause chronic pancreatitis and diabetes is not demonstrable in these cases. The persistence of digestive symptoms after a gall-stone operation may occasionally be due to such diverticula.

# ABSTRACTS

HUMPHREYS, E. M., AND KATO, K.

*Glycogen Storage Disease (Thesaurismosis Glycogenica)* Am. Journal of Pathology, 10,5,589 (Sept., 1934).

Glycogen storage disease, a disease first described by von Gierke in 1929, is characterized by the large size of the liver and kidneys due to the accumulation of extraordinary amounts of glycogen in the parenchyma cells of these organs. The same infiltration takes place in a less frequent number of instances in the heart. Thus has there been described a hepatomegalic or a hepatonephromegalic and a cardiomegalic type of the disease. The authors report four cases of the latter type, making a total of 15 cases of both types now reported in the literature.

The disease is a disorder of infancy and childhood. It affects both sexes and is possibly familial. It is characterized anatomically by organ enlargement and the storage of glycogen chiefly in the enlarged organs. The affected organs may attain great size and may contain glycogen in unprecedented amounts. This glycogen storage is usually not associated with degenerative or proliferative structural changes in the tissues. At least in the hepatomegalic type studies seem to point to an impairment of the mechanisms concerned in the mobilization of the glycogen and the regulation of the blood sugar as the cause. Less is known about the cardiomegalic type of the disease. In the four reported cases by the authors the hearts were 3.3 to 7 times the normal weight (infants ages 4 months heart weight 90 grams, 3 months 140 grams, 5½ months 128 grams, 8 months 260 grams respectively). The myocardial fibers were enlarged, vacuolated and in three cases filled with glycogen. In one case the liver and kidneys were similarly affected but to a lesser degree. In two cases the skeletal muscles showed vacuolar degeneration and in one of these the vacuoles contained much glycogen.

It is most commonly assumed that glycogen storage disease represents a prolongation of foetal or infantile behavior with respect to the metabolism of carbohydrates. The cause and mechanism of it are thus far, however, purely conjectural. It is an infantile disorder probably congenital and possibly familial. Most congenital or familial metabolic disorders are attributed to abnormal enzymatic functions.

*Gastric Mucin in Treatment for Peptic Ulcer.* Arch. Int. Med., Vol. 55, No. 1, January, 1935, p. 7.

The author reports the results of the use of mucin in peptic ulcer in 555 cases of which 226 are termed intractable, i.e. not controllable by the orthodox methods of treatment. The average duration of sickness is about 8 years. Deducting 61 patients who failed to continue with treatment, the author obtained 70.5% complete relief with mucin therapy. There were 32 complete failures and the remaining were partially relieved. He obtained the most significant results in patients who had had a gastroenterostomy performed on them and later developed a recurrence of symptoms. Out of 56, 36 obtained complete relief, 16 partial and 4 obtained none whatever. The author stresses the importance of the preparation of the mucin for the patients use. These reports were made to the Committee on Mucin Therapy by physicians all over the country. A typical report sheet is shown in the text.

In his comments on mucin the author quotes extensively from recent literature in which the possible buffer action of mucin is discussed. While there seems to be consider-

able doubt as to the neutralizing effect of mucin on hydrochloric acid, or even on the depressive action on acid production, nevertheless evidence is adduced to show that mucus acts as a protective agent on the stomach, retards gastric digestion experimentally on the frog leg and inhibits the action of pepsin. The author quotes A. F. Hurst, who called attention to the deficiency of mucus in 10% of all young normal individuals in whom these factors and the presence of hyperacidity and hypertonic stomachs predispose to ulcer formation. This is a debatable question because a large number of patients with ulcer do not have hypertonic stomachs and several no hyperacidity. At the present time the manufacturers are careful to assay the products for its buffer value, test it for its secretagogue value, remove the irritating amines and the disagreeable odor and taste.

*Hepatitis and Cholecystitis in the Course of Brucella Infection.* Arch. Int. Med., Vol. 54, No. 5, November, 1934, p. 702.

Brucella infection in man is relatively a common disease in the United States. There is, however, comparatively little found concerning the visceral manifestations.

A case history is given in full, the abdominal symptoms being severe constipation, pain in the right upper quadrant, marked hyperesthesia of the skin to the right of the mid abdominal line below the umbilicus and the right costal margin. Spasm of the muscles in this region, and pain on deep palpation. A cystic mass could be felt in the region of the gall-bladder. A diagnosis of Acute Cholecystitis was made. Over a period of five weeks there was a gradual subsiding of the biliary tract symptoms, specimens of bile secured by duodenal drainage failed to show bacterial growth on culture.

At surgery, a thickened gall-bladder with adhesions to the liver and duodenum was found. In the left lobe of the liver a small round nodule 1 c.m. in diameter was removed. It was white, with central softening, and had a granulomatous appearance.

Microscopic examination of the tissues of the gall-bladder showed an eroded mucosa, edema of the walls and early granulomatous patches were found. Section of the liver showed the typical nodules produced in animals infected with the disease.

The culture yielded a growth of Brucella Melitensis from both the submucosa of the gall-bladder and the granulomatous process in the liver. Result complete recovery.

Interpretation: In Brucelliasis the continuation of the clinical picture, signs and laboratory evidences may be due to a cholecystitis and focal hepatitis.

*Neurogenic Erosions and Perforations of the Stomach and Esophagus in Cerebral Lesions. Report of 6 cases.* Arch. Int. Med., Vol. 54, No. 6, December, 1934, p. 916.

In 1859, Von Rokitansky described forms of softening of the stomach, frequently associated with acute affections of the brain, especially tuberculous meningitis and hydrocephalus.

Cushing, in 1932, described gastromalacia and ulcers of the upper portion of the gastro-intestinal tract definitely related to disease of the interbrain.

Six cases are presented:

(1) Abscess of the frontal lobe, terminal meningitis gastromalacia with perforation of an ulcer near the fundus on the anterior surface. Digestion of the diaphragm with pyothorax.

(2) Acute encephalitis with marked disturbance of the vegetative nervous system, multiple erosions of the stomach and perforation of the esophagus.

(3) Tumor of the posterior fossa, sexual precocity gastromalacia, perforation of the stomach and diaphragm, localized peritonitis and acute pleurisy.

(4) Infant, 14 hours old, extreme congestion of the brain; superficial necrosis of the pyloric mucosa.

(5) Tumor of the corpus callosum, anterior gastric hemorrhage, gastromalacia with a perforation near the cardia.

(6) Hypertensive cardio-vascular disease with hemorrhage into the basal ganglia, gastromalacia, esophagomalacia and rupture.

The cases seem to bear out Cushing's hypotheses of a parasympathetic center in the diencephalon where Beattie has also demonstrated a sympathetic center.

Stimulation of these centers results in softening and ulcer formation in the stomach.

DONCHES, JOSEPH C., AND WARREN, SHIELDS.

"Chronic Cicatrizing Enteritis, with Involvement of the Caecum and the Colon." *Arch. Path.*, 18:22-29, July, 1934.

Chronic cicatrizing enteritis has also been described under the name of regional ileitis and of nonspecific granuloma of the intestine. This condition was first described by Braun in 1909, but has received increasing attention and emphasis in recent years by Mock, Crohn, and others.

The exact etiology of this condition is not known definitely. Several etiological factors have been suggested. Among these are inflammatory processes starting in the appendix, and also certain types of suture material used in abdominal operations.

The area of intestine involved is most frequently near the ileo-caecal valve, although the lesion may localize in other areas of the small intestine or colon. From the standpoint of pathology, the involved area of intestine usually presents (1) considerable thickening of the wall of the intestine with chronic inflammatory tissue, (2) ulceration of the mucosa, and (3) stenosis of the lumen. This area is also usually adherent to the adjacent structures.

The symptomatology is often vague, although frequently symptoms are present which point to partial intestinal obstruction. The presence of a palpable mass is rather frequent. Roentgen ray findings often simulate those of an obstructing malignant lesion. In fact, the chief importance of this condition lies in its mimicry of carcinoma.

The authors report a single case of particular interest because the caecum and entire ascending colon were involved without any appreciable change on the proximal side of the ileocaecal valve, other than muscular hypertrophy of the wall of the terminal ileum and dilatation. These changes were due obviously to the caecal obstruction. At operation a mass of chronic inflammatory tissue

and fat was found surrounding the caecum. This was thought at the time to be carcinoma. The ascending colon was markedly thickened and shortened, with a constricted lumen and a partially eroded mucosa. The terminal ileum, caecum, ascending colon and proximal part of transverse colon were resected. On microscopic examination the mucosa of the caecum and ascending colon was atrophic where present. It showed metaplasia of the epithelium, but no malignant change. The deeper layers showed extensive fibroblastic proliferation, edema, and infiltration with polymorphonuclear leukocytes, lymphocytes, plasma cells and eosinophils. The appendix appeared to be buried in the mass of chronic inflammatory tissue surrounding the caecum. (The history of previous, repeated attacks of "abdominal cramps" in this patient suggested probable mild attacks of appendicitis).

The authors also review briefly twenty-four cases of chronic cicatrizing enteritis found in the literature.

BEAVER, DONALD C.; HENTHORNE, JOHN C., AND MACY, JOHN W.

"Abscesses of the Liver Caused by *Bacteroides Funduliformis*." *Arch. Path.*, 17:493-509, April, 1934.

Two cases of hepatic abscesses caused by *Bacteroides funduliformis* are presented. The previous literature upon this type of infection is also reviewed. The genus *Bacteroides* includes certain anaerobic, non-sporulating bacilli. Seventeen species have been listed, some of which are gram-positive and others gram-negative, some motile and others nonmotile. *Bacteroides* are normal inhabitants of the intestinal tract of man.

*Bacteroides* infection may lead to serious suppurative and gangrenous lesions in man. Primary lesions occur most frequently in the large intestine and in the genito-urinary tract. Colonic lesions usually originate either in infected carcinomas or in the crypts. Direct hematogenous dissemination of the infection from the colon to the liver may develop, leading to hepatic abscess formation. Primary lung lesions may also occur, usually upon the basis of aspirated infection. Pulmonary lesions may consist of septic infarcts, patches of bronchopneumonia, or putrid, gangrenous abscesses of variable size.

The clinical syndrome of *Bacteroides* infection is that of an extreme degree of sepsis, with a high, remittent type of fever, chills, perspiration, and exhaustion. The physical findings will vary with the localization of the lesions.

In the first case reported by the authors, at autopsy the primary lesion consisted of an infected ulcerating carcinoma of the rectum. Certain of the adjacent veins were invaded by carcinoma, and also contained infected thrombi. Abscesses of the liver were found in close association with carcinomatous-metastases of the liver. Portal thrombosis was present.

In the second case large, multilocular, hepatic abscesses were found, confined within the right lobe of the liver, and suggesting dissemination by way of the portal circulation. It is probable that the hepatic abscesses in this case arose from a cryptic focus somewhere in the large intestine.

The authors review the detailed pathological and bacteriological findings in these two cases, as well as the results of animal tests for pathogenicity of the organisms.

## SECTION II—*Experimental Physiology*

### Studies on the Neutralization of Gastric Acidity: Ewald Test Meal and X-ray (Barium Meal) Studies in Patients with Duodenal Ulcer, Gastro-jejunostomy and Gastric Resection

By

ROBERT ELMAN, M.D.  
ST. LOUIS, MISSOURI

and

J. WENDELL MacLEOD, M.D.  
MONTREAL, CANADA

THE acidity of gastric contents as a factor in the pathogenesis and treatment of peptic ulcer, particularly of the duodenum, has long been considered of great importance. Clinical study of acidity has been, to a great extent, disappointing, due largely to the wide variations in acidity which are found in gastric contents both of normal and diseased patients as shown by Keefer and Bloomfield (1) in spite of the trial of many types of stimuli or test meals to evoke secretion. This lack of uniformity has not only discouraged its clinical use in estimating normal secretory function, but has detracted from its diagnostic value in indicating pathological changes. As a consequence, greater reliance has been placed in recent years on studies of gastric morphology and motor function as revealed by the x-ray after ingestion of a barium meal.

The present study is an attempt to investigate the acid factor by means of a relatively new functional test. Instead of measuring the acid secreted in response to a stimulus it will be concerned with the neutralization of acid introduced in solution directly into the stomach. The findings obtained will be compared with the results of the usual fractional Ewald test meal and both will then be correlated with the

clinical picture in each case and also with the observations made in the dark room from fluoroscopic study after the ingestion of barium.

The theoretical basis for the use of a neutralization test in the study of gastric acidity is twofold. The acidity of stomach contents obtained after a test meal, first of all, is not that of gastric juice secreted as such, but is the resultant of secretion and neutralization. This is apparent from the fact that pure gastric juice as actively secreted both in animals and in the human being (2) is of a high and constant acidity (i.e. .5% HCl or 135 degrees) whereas, as observed clinically in the normal individual it rarely goes above half this figure. Whether it is food, mucus, neutral chloride or regurgitated alkaline pancreatic juice which is responsible for this neutralization is another problem; suffice it to say that whatever it is the rôle it plays in governing and regulating gastric acidity, though important, is one which escapes direct estimation in the ordinary test meals. A second reason for the use of a neutralization test is that one is not always sure that test meals really test; that is, that the stomach has actually been stimulated by the method designed to do so, or that, even if the test has evoked a secretory response, the effect is of a magnitude approaching normal function. To do so one should really

Fig. 1. Composite graph of neutralization tests in patients with symptomatic duodenal ulcer confirmed by x-ray study. Note incomplete neutralization as compared with normal. Clinical details are recorded in Chart I. The vertical lines represent the acidity of gastric contents both fasting and secreting, the latter representing the highest value obtained after administration of the test meal. See Chart I).

allow the patient to eat a regular meal under normal circumstances before measuring the resulting acidity. With the neutralization test consideration of the secretory response is excluded for the acid is introduced at once; only the single mechanism of neutralization is measured. This is not entirely so for the introduction of fluid of any kind by mechanical distensions of the stomach wall has been shown to constitute a gastric stimulus. (3) In this case the amount of fluid used is small (300 cc.) and the magnitude of the stimulus is thus very slight.

#### PREVIOUS OBSERVATIONS

Migai, (4) in 1909, was probably the first to introduce acid gastric juice from a dog and also HCl solutions into the human stomach and he found that neutralization thereof proceeded rapidly and completely. Boldyreff, however, was really responsible for the use of such a test solution of acid in experiments designed to measure the acid regulating power of the stomach which he claimed occurred normally because of the regurgitation largely of alkaline pancreatic juice into the stomach (5). Spencer, Meyer, Rehfuess and Hawk (6) furthered the theory of Boldyreff by many studies, some of which involved the introduction of 100 cc. of .4% HCl (110 degrees) into the human stomach. They, too, found that it was promptly neutralized. Apperly (7), in 1926, introduced 400 cc. of a weaker acid solution (.3 to .35% HCl or 80 to 100 degrees) into the stomach and observed the same effect. MacLean and Griffiths (8) used similar acid test meals for functional studies of gastric physiology. Palmer (9) introduced 50 cc. of stronger HCl solution (135 degrees), but did not study its neutralization; he noted only its effect on the reproduction of symptoms. In addition to these clinical studies acid solutions have been given to animals by many observers including, besides Boldyreff, Burget and Steinberg (10), Mathews and Dragstedt (11),

Elman (12) and Olch (13). Its behavior in the normal dog's stomach was the same as that in the normal human stomach; that is, the acidity was rapidly and promptly neutralized. In general, however, in all of these studies the use of the acid solution was incidental to a special problem; its use in obtaining functional and diagnostic data was not investigated.

Apperly and Cameron (14), in 1923, proposed and used a test solution of 250 cc. of .4% HCl (110 degrees) as a measure of the neutralizing (alkali producing) power of the pancreas, since they assumed that neutralization was due to regurgitation of alkaline pancreatic juice. The first to study peptic ulcer cases with the acid neutralization meal was one of the present authors (R.E.). A definite delay in the neutralization of the acid solution over the normal was noted (15) in twelve cases of proved duodenal ulcer. After gastroenterostomy, moreover, this mechanism was accelerated so that the acid solution introduced was neutralized much more rapidly even than in normals. More recently J. L. Levy (16) used the same test in a series of patients with pyloro-duodenal disease and presented data which pointed to its definite value as a diagnostic test which seemed more uniform than single acid values obtained 45 minutes after giving an Ewald meal and more closely related to the clinical picture and x-ray findings.

#### METHODS

A group of unselected patients with a diagnosis of duodenal ulcer was obtained from the gastro-enterological clinic of Washington University; of those under medical treatment with definite x-ray evidence of ulcer most were studied at a time when they were having definite symptoms; a few, however, were entirely free of symptoms. Then there were patients in whom a gastro-enterostomy had been done for duodenal ulcer which was verified by operation. A few patients with gastric resection were also studied. They had had gastric ulcers (one had a gastric carcinoma). All the operated patients were symptom free. With the exception of three patients (Cases 23, 24 and 25) months or years had elapsed since operation.

Fig. 2. Note normal neutralization curves in patients with duodenal ulcer as shown by x-ray but who are having no symptoms. (See Chart II).

Finally three patients who had symptoms of duodenal ulcer, were found to show no x-ray evidence thereof; they were kept in a separate group. Observations, however, were made without regard to these groupings.

The routine examinations were made as follows: At the first visit a barium meal was given and the patient studied fluoroscopically until the stomach was empty; at the second visit the neutralization test was done; at the third visit a fractional test meal was carried out. Most of the patients were subjected to these observations at intervals of one week between visits. The usual preparation of fasting before each examination was made. For the

will be briefly summarized below and discussed in more detail further on.

Several "normal" patients with normal neutralization curves were studied, but are not shown since they agree with those already reported in a previous observation (15). That they show a rather uniform regularity has also been confirmed by Levy (16). The solid line used in each test figure as the normal was obtained from the communication already mentioned (15). This same "normal" curve was noted in three patients with history and x-ray evidence of duodenal

x-ray a barium meal was made with 400 cc. of buttermilk plus 120 gm. of barium sulphate. Many of the patients had in addition serial x-ray studies which included films. Shredded wheat biscuit and 400 cc. of water were used for the Ewald test meal and 300 cc. of .5% HCl (135 degrees) for the neutralization test as described in detail previously (15).

## FINDINGS

On the basis of the clinical picture the 25 patients fell into the groups as mentioned above: (1) Symptomatic ulcers—8 cases; (2) quiescent ulcers—3 cases;

ulcer (presumably healed), but who were having no symptoms even though they were taking no special treatment see (Chart 2 and Fig. 2).

Of the other patients, Group 1 contained eight ulcer cases who were having symptoms (some in spite of medical treatment, many on no treatment at all). They all showed delayed curves indicating faulty acid neutralization. Some also showed marked retention (not shown in the figures). The third and fourth groups comprise those operated on and as can be seen (Figs.

(3) postoperative gastro-jejunostomies—7 cases; (4) gastric resections—4 cases; and (5) syndrome of ulcer without x-ray evidence—3 cases. Details of their clinical features and x-ray findings are presented in Charts 1 to 5; the acidity studies are represented in corresponding Figures 1 to 5 which show composite graphs of the acid neutralization curves as well as the titration values of both fasting contents and the highest point reached during the test meal. These charts are largely self explanatory. The findings, however,

3 and 4) the neutralization of the acid is more accentuated than normal; this is especially true of the gastric resections. A secondary rise in acidity of three of the patients with gastro-enterostomy is of special interest and will be discussed later. The three patients with duodenal ulcer symptoms (Group 5) all showed delayed curves even though the x-ray showed no positive evidence of ulcer.

Three acid values are shown in the text figures; two represent the fasting contents obtained before

Fig. 3. Note the more rapid neutralization than normal in patients with gastroenterostomy. The terminal rise of the curve in three cases is discussed in the text. (See Chart III).

starting the Ewald and the neutralization test. The third value is the highest acid titration from the fractional aspirations obtained after giving the shredded wheat biscuit. It will be seen that by comparing the two fasting values there is considerable variation in individual cases. The highest acid values also vary in each group, not only between each other, but also when compared with the results of the neutralization test. Moreover, in a number of cases the fasting acid value was greater than that reached after the test meal.

The results of the x-ray study are shown in the charts and comprise information as to the emptying time, appearance of, and tenderness over the cap, residual fluid and activity and appearance of the stoma (in the operated cases).

#### COMMENT

The importance of the findings recorded herein lies in the fact that they point to the usefulness of a test for measuring the rate of neutralization of acid within the stomach. The series of cases, though small, yielded fairly uniform results. The value of the test may be best considered (1) by comparing it as a measure of the behavior of gastric acidity with the results of the fractional test meal and (2) by comparing it as an indication of gastric functional disability with the x-ray findings and the clinical picture.

That the neutralization test should give a better estimate of the behavior of gastric acidity than study of gastric contents obtained following the use of an Ewald test meal has been suggested on the basis of the theoretical considerations already mentioned. Actually the findings bear out this contention as perusal of the various charts and test figures will show.

This is particularly true of Group 1. While it will be seen that the test meal acidity is in general high in these ulcer cases with symptoms (Fig. 1) there are notable exceptions. Thus, Case 15 had subnormal acid values of 0°, 10° and 20°, yet the neutralization test showed a high level of acidity indicating a faulty neutralization which agreed rather well with the severe symptoms this patient had (Chart 1). Two of the cases (No. 7 and 12) had acid values in the upper level of normal and only two had really high values above 100° (Cases 8 and 9), yet the neutralization curves all showed delay in the neutralization of the acid test solution.

Of much interest were the cases with gastro-enterostomy (Chart 3). In them the test meal acidities were within relatively normal limits (Fig. 3). The neutralization test, on the other hand, showed a reduction of gastric acidity more rapid than normal; this agreed with the findings already reported in another series of cases (15) and reflects perhaps the beneficial physiological effects of the operative procedure. The terminal rise of the curve in cases 1, 4 and 16 were of special interest; it did not occur in previous observations (15). One of them (Case 1) was beginning to have mild symptoms (slight hunger pains relieved by food). The patient with the most marked terminal rise (Case 16) showed under the fluoroscope (see Chart III) a stoma which was high and proximal, a poor position for a gastroenterostomy, through which clearance was poor. This is the only patient with such a finding; it suggests that the presence of the terminal rise in the neutralization curve may be connected with an inadequate function of the stoma. On the other hand a slight terminal rise was noted in one unoperated patient (case 2 of the first group). Further observations will have to be made.

Fig. 4. Note the very rapid neutralization in all but one of the above curves obtained from patients with gastric resection. (See Chart IV).

Fig. 5. Note the incomplete and almost absence of neutralization in patients with characteristic ulcer symptoms but who showed no direct evidence of ulcer by x-ray. (See Chart V).

In the gastric resections (Fig. 4) the fasting and test meal acid values were all close to zero. While three of them showed very rapid neutralization rates it is of interest to note that one of them showed a rather normal curve (Case 18). In the final Group 5, the Ewald test meal was only done in two of the three cases. It is suggestive that in both the results were within normal limits, even though the symptoms were marked and the neutralization test showed a high level i.e. faulty neutralization, similar, in fact, to the cases with definite x-ray evidence of ulcer in Group 1.

Another finding worthy of note was the fact that the acid values of the fasting contents were not infrequently higher than the highest figures obtained after the test meal of shredded wheat biscuit (see Cases 2, 3 and 11 in Fig. 1; Case 14 in Fig. 2; Case 4 in Fig. 3; and Case 21 and 22 in Fig. 5). This bears out one of the theoretical objections (mentioned above) to the usual form of gastric analysis; that is, that the stimulus designed to provoke secretion does not always do

so the acidity of the fasting contents in these cases was so, or that it falls short of what occurs normally. That higher indicates that the test meal failed to provoke a really active secretion for it would be inconceivable that an organ would secrete more while fasting than while working.

As an indication of functional disability the neutralization test seems of especial value in that the findings after its use agreed with the clinical picture as well as, and in many cases better than, the results of x-ray investigation. Thus, in Group 1, the patients with the worst symptoms had the highest acid curve; that is, most faulty neutralization (Cases 12 and 15), yet the x-ray in both of these cases showed no retention and no tenderness over the cap. The case with the mildest symptoms (Case 7) had a curve which approached the normal closer than any of the others; in this case the x-ray also reflected the relative mildness of the lesion. In the three cases of Group 2 the evidence of ulceration by x-ray was definite, yet the neutralization curve was normal; the absence of symptoms in these patients suggested perhaps that the ulcers were healing. On the other hand, in the three patients of Group 5 the neutralization test showed faulty neutralization, the curve being similar to those of the patients with definite ulceration, and indeed they were having classical ulcer symptoms. Yet x-ray showed no positive evidence of an anatomical lesion. It is suggestive, however, that in these patients gastric residual fluid and gastric retention were noted by x-ray and one showed a "quick" cap which, however, later showed perfect contour. Very likely these patients had a perversion of function (pylorospasm?) which leads to ulceration; the neutralization test, thus, would seem to indicate rather early evidence of disease. Such patients may be on their way toward the formation of an ulcer later. Many, however, clear up under medical treatment and two of the three patients in this group were getting relief. More of them will be studied and reported later, particularly as to the effect of symptomatic relief on the neutralization test.

#### SUMMARY

1. Gastric studies of 25 patients were made by means of x-ray (after a barium meal), fractional Ewald test meals and neutralization curves of gastric acidity. The patients comprised those with x-ray evidence of ulcer, both with and without symptoms, those with symptoms of ulcer but with negative x-ray findings, and those with gastro-enterostomies and gastric resections.

CHART IV  
Gastric Resection

| Case | Sex and Age | Symptoms | X-ray Findings                                    |                |            |               |
|------|-------------|----------|---------------------------------------------------|----------------|------------|---------------|
|      |             |          | Residual Fluid                                    | Stoma          | Tenderness | Emptying Time |
| 13   | F 30        | None     | 0                                                 | Functions well | 0          | 2 hours       |
| 15   | F 28        | None     | 0                                                 | Functions well | 0          | 2 hours       |
| 19   | F 45        | None     | 0                                                 | Functions well | 0          | 3 hours       |
| 23   | M 60        | None     | 14 days after operation for carcinoma of stomach. |                |            |               |

2. The findings obtained by means of the neutralization test suggest that it is a more useful method of studying gastric acidity than is the Ewald fractional test meal since it gives more uniform results.

3. As an indication of perverted function the neutralization test shows closer agreement with the clinical picture in many cases than with other tests including the x-ray.

CHART V  
*Ulcer Symptoms (X-ray negative)*

| Case | Sex and Age | Symptoms                                                                          | X-ray Findings |                                                        |                   |                 |                           |

## ABSTRACTS

REIFENSTEIN, EDWARD C., and ALLEN, ELLERY G.

*The Treatment of Chronic Hemolytic Jaundice With Liver Extract. J. A. M. A.*, 103:6068 (December 1, 1934).

Splenectomy has long been considered to be the most successful accepted therapeutic procedure in the treatment of chronic hemolytic jaundice. The fragility of the erythrocytes persists after operation and hemolytic crises have recurred in some cases.

Because of these occasional failures and because the patients readily die from the disease, some clinicians have adopted a conservative attitude in its treatment.

Liver extract was used by various authors in some of these cases. The results, as gleaned from the literature, have been conflicting. For this reason the authors felt that further studies as to the value of liver therapy in chronic hemolytic jaundice was justified. They cite three cases of chronic hemolytic jaundice treated with liver extract, all of them showed clinical improvement. In one case, clinical improvement occurred but the increase of icteric index, urobilinuria, and increased fragility of erythrocytes persisted, while the anemia improved. The other two cases showed no definite or sustained increase in fragility of the red cells, though similarly treated, but the disappearance of a mild anemia, jaundice, and urobilinuria were noted.

Francis D. Murphy, Milwaukee, Wis.

PEARSE, H. E.

*Experimental Chronic Intestinal Obstruction from Blind Loops, S., G., and O.*, 59:726, 1934.

On 60 dogs the author studied the fate of blind loops after jejunal enteroanastomosis and obstruction. The results were as follows:

1. That portion of bowel below the obstruction where the peristaltic action was directed away from the blind end toward the anastomosis remained empty.

2. In the segment above the obstruction where the peristaltic current was from the anastomosis toward the blind end, material was carried into and retained in the blind segment. If this loop was one foot or less, it emptied itself and did not become dilated. If this blind loop was two feet long, it became dilated and filled with inspissated material. This, however, caused no symptoms. If this blind loop was three or four feet long, enormous hypertrophy and dilatation followed. If perforation did not occur, chronic intoxication resulted after 3 or 4 months. Resection of this blind loop allowed complete recovery of the animal. Blind loops five or six feet long subtracted such a large part of the total intestinal length that the majority of the animals died from inanition and dehydration.

K. Hosoi, New Orleans.

## SECTION III—Nutrition

### Glycosuria and Lactosuria of Pregnant and of Lactating Women

By

HENRY J. BROCK, M.D.

and

ROGER S. HUBBARD, Ph.D.

BUFFALO, NEW YORK

**D**URING the last 75 years interest has been taken in the excretion of sugar by women during pregnancy and lactation. It has long been known that lactosuria occurs in these conditions, but exact study has been greatly hampered by a lack of suitable analytical methods. In the present communication, a method capable of demonstrating lactose in concentrations as low as 5 to 10 mg. per 100 cc. will be described, and the results of its application to a series of urine specimens from pregnant, lactating, and normal women will be discussed.

#### HISTORICAL RESUME

Blot (1), (1856), found a reducing substance in the urines of 50 per cent of the gravid and nursing women whom he studied, and Hofmeister (2), (1877), showed that the substance present was lactose. Since that time much work has been done, and many methods for studying the sugar quantitatively have been developed. A complete review of this literature will not be attempted here. Instead, a few of the more recent papers will be discussed; readers are referred to the bibliographies of these for further detailed information.

Snock (3) has relied chiefly upon the formation of the osazone, and has used fermentation with yeast as a corroborative analytic method in some instances. This method cannot be applied accurately when lactose is present in concentrations lower than 0.1 per cent; especially is it unsatisfactory when a mixture of sugars is present. Winter (4, 5) abandoned this procedure, and substituted one based upon the specific rotation, melting point, and solubility of glucose and of lactose. His methods served to identify the sugars, but gave only approximate estimations of the amounts present. Kowarski (6), Gootz and Tunger (7), and others have determined the reducing power of untreated urine, and have repeated the analyses after hydrolysis. By such a technique it is difficult to distinguish one polysaccharide from another, for all may cause similar increases in reducing power after they have been hydrolized. Kleiner and Tauber (8) recently have described a rather simple and practicable

procedure. Using appropriate copper reagents, they determine the total reducing sugars and the monoses in urine. The authors did not determine amounts of sugar which were present in concentrations lower than 0.05 per cent, and they did not differentiate various disaccharides from one another when more than one sugar of this type was present. Castellani (9, 10, 11) and others (12) have demonstrated lactose in urine by differential fermentation with yeasts and organisms. 0.05 per cent was the lowest concentration they could demonstrate by the technique which they used. Harding (13, 14, 15, 16) and his co-workers used a somewhat similar procedure for showing the presence of lactose in urine or in a mixture of sugars. Hubbard and Kingsbury (17) combined Castellani's bacteriological fermentation with the blood sugar method of Folin and Wu (18), and were able to determine lactose quantitatively when it was present in blood in concentrations as low as 0.005 per cent. The method which we have used for determining lactose in urine is based upon similar principles.

#### DESCRIPTION OF ANALYTIC METHOD

**Apparatus:** (1) 50 cc. beakers. (2) Small watch glasses to cover beakers. (3) Folin-Wu sugar tubes. (4) 1 cc. pipettes calibrated in gradations of 0.01 cc. (5) Sterile 1 and 2 cc. pipettes. (6) 3 cc. pipettes. (7) Sterile, cotton-plugged 15 cc. centrifuge tubes. (8) Sterile agar slants in 6 in. test tubes. (9) Incubator.

**Reagents:** (1) Heavy suspension of *B. Coli* and *B. Proteus*. These suspensions are made in the following way: agar slants are heavily inoculated with organisms and incubated for 24 hours; 2 cc. of sterile distilled water then is poured over each slant with sterile 1 cc. pipettes; the organisms thus are freed from the surface of the agar and suspended in the water by the aid of a sterile platinum loop; the suspensions should be used at once. The *B. Coli* ferment all the common sugars (glucose, fructose, lactose, galactose, maltose, xylose, arabinose) and *B. Proteus* ferments all except lactose and xylose. Differential fermentation with these organisms therefore furnishes a method for determining lactose and xylose, even when they are present only in traces, in a solution containing very large amounts of other sugars. Since xylosuria apparently does not occur (Foot-note 1), the organisms can be used for determining lactose in urine.

(1) Formerly it was believed that xylose was excreted in most cases of pentosuria. Recent investigations have shown that the sugar present in this condition is xylo-ketose, which does not interfere with the method described as it is not fermented by *B. coli*.

\*Preliminary report was read before the Buffalo Pathological Society in November, 1934.

†From the Buffalo General Hospital and the University of Buffalo Medical School, Buffalo, New York.

Submitted December 7, 1934.

(2) Dinitrosalicylic acid solution (Sumner 19) "To 300 cc. of 4.5 per cent carbonate-free sodium hydroxide add 880 cc. of 1 per cent dinitrosalicylic acid and 255 gms. of Rochelle salt ( $\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ ), mix until dissolved, and keep tightly stoppered. Dinitrosalicylic acid can be prepared as described in a previous paper (20) or can be obtained from Eimer and Amend or from the Eastman Kodak Co."

(3) Standards. Dissolve 0.800 gms. of lactose in a liter of distilled water. One cc. of this solution contains 0.0008 gms. (0.8 mg.) of lactose.

**Method:** Place approximately 10 cc. of urine in a 50 cc. beaker (Foot-note 2). Cover with a watch glass and boil for two minutes to sterilize. The following procedures should be carried out with precautions which will insure the preservation of sterility: Pipette 2 cc. of urine into each of 3 cotton-stoppered 15 cc. centrifuge tubes. Add 0.5 cc. of a heavy suspension of *B. Coli* to the first tube, 0.5 cc. of a similar preparation of *B. Proteus* to the second, and 0.5 cc. of sterile distilled water to the third (control) tube. The same pipette can be used for 6 or 8 inoculations with the same organism, but precautions must be taken to avoid mixing the cultures. Incubate for 12 to 16 hours at 38° C. After incubation sterile precautions need not be taken. Dilute the contents of each tube to 3 cc. with distilled water. Mix. Centrifuge if cloudy. Measure 1 cc. of the contents of each tube into a Folin-Wu blood sugar tube. Prepare standards by measuring 1, 0.5, 0.25, and 0.125 cc. of the standard lactose solution, containing respectively 0.8, 0.4, 0.2, and 0.1 mg. of lactose, into Folin-Wu sugar tubes. Add to each standard enough water to give a total volume of 1 cc. To each of the sugar tubes containing standards and aliquots of urine add 3 cc. of

the dinitrosalicylic acid solution. Immerse the tubes in a boiling water bath for 5 minutes. Cool. Dilute the contents of all tubes to 25 cc. Mix. Compare the color of each of the unknown solutions with that of the standard nearest to it in tint in a colorimeter.

**Calculation:** The reducing power of the contents of each tube is calculated by means of the following formula:  

$$\frac{\text{reading standard}}{\text{reading unknown}} \times \text{value of standard} \times 1.5 \times 100 = \text{mg. reducing substances in 100 cc.}$$
 If the urine was diluted before it was analyzed, the results must be multiplied by a factor to correct for the degree of dilution. By this calculation all results are given in terms of the lactose equivalent to the reducing substances present. To find the amounts of the different sugars calculate as follows:

The color in tube A is due to residual (non-sugar) reducing substances.

The color in tube B is due to residual reducing substances + lactose.

The color in tube C is due to residual reducing substances + lactose + other fermentable sugars (glucose).

Tube "A" is the one treated with *B. Coli*, tube "B" the one inoculated with *B. Proteus*, and tube "C" the control tube.

mg/100 cc. reducing substances in B — mg/100 cc. reducing substances in A = mg. lactose per 100 cc. urine.

mg/100 cc. reducing substances in C — mg. 100 cc. reducing substances in B = mg. other (non-lactose) fermentable sugar per 100 cc. urine. "Other sugars" are given in terms of lactose by this calculation.

The result can be converted into terms of glucose, which is the sugar almost always determined, by multiplying by the factor 100/124 for both Sumner (19) and the authors have found that 124 mg. of lactose gives the same color as 100 mg. of glucose when dinitrosalicylic acid is used for determining the sugars.

By the method described, amounts of lactose as great as 200 and as small as 5 mg. per 100 cc. of urine

TABLE I  
Concentrations of sugars in urine

could be determined when the urine was not diluted before analysis. When dilute solutions of urine were studied, the method was applicable to very large amounts of lactose. In carrying out the procedure, control tubes containing lactose added to urine to give concentrations of 20 mg. per 100 cc. were routinely inoculated, incubated, and analyzed. The average recovery in 21 experiments of this sort was 99 per cent.

### CLINICAL DATA

The method was applied to the study of urine specimens voided between 10 and 11 o'clock by women who, in the most instances, had eaten breakfast. Pregnant women, lactating women, and a control series of women between the ages of 18 and 45 from the wards and Out Patient Department of the Buffalo General Hospital were included. The specimens of urine from pregnant and lactating women were obtained from cases on the service of Dr. F. C. Goldsborough. As a part of the investigation, 290 specimens of urine from pregnant women on this service were tested with Benedict's qualitative reagent. Sixty-eight, or 23.4 per cent, of these gave a reaction interpreted as positive. Snoeck (3), in a similar series, found that only between 3 and 5 per cent gave positive reactions. It seems probable that slight differences in technique and in the interpretation of results explain the difference between the figures. Fifty-four per cent of 90 urine specimens obtained from women after delivery gave positive reactions. Of the control series, selected because the age and sex made them fairly comparable with the others, 12 per cent gave positive reactions with Benedict's solution. In Table I the results of the quantitative studies made are presented.

### DISCUSSION

The results given in Table I can conveniently be grouped for discussion according to the three types of cases studied. The series used as a control seems to be unique, for no other attempt at quantitating the lactose in the urine of women who were neither pregnant nor lactating was found in the survey of the literature made.

Twenty-four women were studied. Eighteen of these gave results which were negative—which at least were lower than was the concentration determined by our method—but three specimens contained definite traces of lactose (Foot-note 3). The highest concentration found was 13 mg. per 100 cc. of urine. It seems probable that these traces were of alimentary origin, since there is evidence available in the work of Winter (4), Watkins (21) and of Snoeck (3) that lactosuria can arise in this way.

Practically every one of the control urines contained some sugar which was fermented by both the organisms used. It seems almost certain that this sugar was glucose. The amounts were of the order of magnitude which have been almost regularly found in samples of urine obtained from normal subjects after meals.

*Lactating women:* The findings on lactating women were similar to those of other investigators (Watkins (21), Winter (4), Willway (22), Kleiner and Tauber (8), Nizza (23), Castellani (10), and Amalfitano and

Roberto (24) who have studied this problem. Lactose was undoubtedly present in 11 of the 12 specimens analyzed (92 per cent), and the remaining specimen apparently contained 9 mg. per cent of lactose, a value which we have decided to include in the questionable range (Foot-note 3). The percentage of positive values is higher than that reported by some previous observers; this probably results from the great delicacy of the method which we used.

This series, which was carried out primarily as a control upon the studies of pregnant women, is too small to serve as a basis for an extended study of variations in the degree of lactosuria in different stages of lactation. Table II has nevertheless been prepared, and is given because it demonstrates that

TABLE II  
*Concentration of sugar in urine after parturition*

| Day After Parturition | Number of Cases | Series Number | Reaction with Benedict Qualitative Reagent | Lactose mg 100 cc. | Glucose mg 100 cc. |

| 4 months              | 1               | X             | ++                                         | 57                 | 18                 |

our results were in approximate agreement with those of earlier observers. For example, Watkins (21) and Nizza (23) both found that urinary lactose was low during the first few days after parturition, rose to a peak on the third to the fifth day as the breasts filled with milk, and then gradually declined. It is clear that the results in Table II show similar relationships. The generally accepted explanation of these changes, which seems to be an adequate one, is that stagnation in the breasts occurs during the early days of the puerperium and an absorption of lactose into the blood stream is produced. As the infant begins to nurse regularly and the breasts are practically completely emptied, the lactose overflow is greatly diminished. As shown in Table II, a single analysis was carried out on the urine of a woman who was nursing her child 4 months after delivery. A fairly high concentration of lactose (57 mg. per 100 cc.) was found. Lactosuria may, therefore, persist in some instances for a fairly long period of time after delivery and the urine may contain enough lactose to give a positive reaction with Benedict's reagent, as it did in this instance.

The figures upon the glucose content of the urines from pregnant women are also interesting. It has been stated that sugars other than lactose are absent from the urine of lactating women who show lactosuria. This was not the case in the series presented. The average glucose content was greater in the lactating than in the control group. It seems doubtful whether much emphasis should be laid upon this difference between these averages for a number of reasons. The series was too small to serve as a basis for valid comparisons; the urines of the lactating women con-

(3) In interpreting the clinical data, a figure of 10 mg. per 100 cc. has been arbitrarily chosen as the lowest value showing the presence of a definite amount of lactose. As already stated, results as low as 5 mg. per 100 cc. appear to be significant, but it has seemed better to adopt the more conservative figure for this discussion.

tained such large amounts of sugar that it was necessary to dilute them before carrying out the analysis (Foot-note 2) and the figures for glucose were obtained in most instances by multiplying small determined values by 5; and, thirdly, except for two or three results, the amounts were almost the same in the lactating and control series.

It appears most probable, but not absolutely certain, that lactating women usually excrete approximately the same amounts of sugars other than lactose as do normal women of the same age group. If this is true, it seems improbable that galactose, the sugar from which lactose is in part derived, is present in the urine in any considerable quantity, as this sugar would be determined together with glucose by the method used.

*Pregnant women:* The present investigation was

There seem to be four or five possible explanations for the presence of lactose in the urine of pregnant women. (1) The sugar may be alimentary in origin. The Authors, as already stated, believe that the occasional presence of traces of lactose in the urine of normal women probably can be explained in this way. The low incidence of lactosuria in the control series compared with the relatively large number of positive findings in the pregnancy group seems to exclude such an explanation for the lactosuria of pregnancy. (2) The renal threshold for lactose may be low in pregnancy. If such a condition were present, ingested lactose might be excreted easily by pregnant women, and the results be adequately explained. The frequency with which non-diabetic glycosuria occurs in pregnancy, which has been often discussed, and which is illustrated by the results obtained in this study, might

TABLE III

directed primarily to the study of pregnant women, and the results upon them deserve especial emphasis. Thirty urines, or 71 per cent of the number analyzed, contained significant traces of lactose. Grandhomme (25), and Commandeur and Porcher (26) reported similar findings, but the incidence is much higher than that reported in many papers. It seems probable that this high incidence is due to the delicacy of the method of analysis used; in fact Snoeck (3), (who found that during the whole period of pregnancy 1 per cent of the cases showed lactosuria, and that during the last months a maximum of 7 per cent gave this finding), stated explicitly that higher figures would probably be found when better technical methods were available.

As will be seen in Table III, the averages of the lactose concentrations in the different months was practically constant throughout pregnancy. It is probable that great emphasis should not be placed upon this constancy because the number of urine specimens obtained during the early months was rather small. It is certain, however, as has been reported also by some previous observers, that lactosuria is not infrequent during the early months of pregnancy. The Table also shows that the greatest concentrations of lactose occurred during the latter months, but that negative values were not infrequently found at that time. These results are also in accord with series which have been reported previously. It seems to the Authors especially interesting that negative findings were encountered as late as the tenth month; the negative findings reported previously have frequently meant only that less than 0.05 per cent was present—the lowest amount demonstrated by many of the methods used.

be a point in favor of such an hypothesis, for if the threshold is low for one sugar, it is not difficult to believe that it is low for another also. The Authors do not believe, however, that there is a low threshold for lactose during pregnancy, partly because there was no relationship between the degrees of glycosuria and of lactosuria in the different cases studied, and partly because the renal threshold for lactose is always so low as to be practically zero. A number of blood samples from normal, lactating, and pregnant women were analyzed by a method, to be described in detail later, which will demonstrate lactose in concentrations as low as 1 mg. per 100 cc. of plasma. Negative results were regularly obtained except in blood from a very few lactating women who were excreting large amounts of lactose. The maximum concentration found was 2 mg. per 100 cc. of plasma. (3) A third possibility is that liver damage, which some observers (27, 28, 29) believe exists during pregnancy, may lead to the excretion of lactose as it sometimes does to the excretion of levulose and galactose. This explanation seems improbable for two reasons: (A) Impaired levulose tolerance is not readily demonstrated in normal pregnancy (30), and (B) lactose is practically wholly split in the digestive tract, and very little unaltered disaccharide reaches the liver. If a decreased liver function plays any part in the lactosuria of pregnancy, it is almost necessary to assume also that an unusual amount of unaltered sugar is reaching the liver, either by absorption through the wall of the gut, or from some other source. (4) The fourth possibility is that pregnant women excrete lactose because small amounts of sugar are formed in the mammary glands, which are developing some de-

gree of activity, and that this sugar escapes into the blood stream and urine.

To the Authors the last theory appears to be the most probable one. Their reasons are: (A) that the other explanations offered above seem to them to be inadequate; (B) that our theory accounts adequately for the high incidence of positive findings (71 per cent of all specimens gave results which were certainly positive); (C) that it explains lactosuria in the presence of very low concentrations of lactose in the blood; and, (D) that it seems to the Authors to account adequately for the occurrence of positive results throughout pregnancy and also the presence of the highest concentrations just before parturition. (5) A fifth possible explanation should also be mentioned. Possibly unaltered lactose may pass through the in-

In Tables IV and V the specimens upon which positive and negative reactions with Benedict's qualitative reagent were obtained have been given separately. Specimens with reactions recorded as  $\pm$  are classified with those more strongly positive. For convenience both sugars were expressed as glucose in computing the data. Inspection of these Tables shows that, in our hands, results of this test corresponded quite closely with definite concentrations of total fermentable sugar in urine. All specimens containing more than 60 mg. per cent gave positive reactions, while all but two containing less than 40 mg. gave negative ones. In the two exceptions, which were both urines from pregnant women, it was quite clear that the result was largely due to the unusual amount of non-

TABLE IV

*Concentrations of sugar in urine giving positive reactions with Benedict's reagent*

testinal wall more easily in pregnancy than it does under normal conditions. While this explanation is possibly correct, it appears to the Authors that it is not so probable as is the one based upon activity of the mammary glands which has been discussed above.

It will be seen from Table I that most pregnant women excreted sugar which was not lactose. The average of the figures and the incidence of high values were both markedly higher in this group than they were in the lactating or control group. It seems almost certain that this sugar was glucose, although the presence of galactose cannot be excluded. It has long been thought that a benign glycosuria due to glucose occurs frequently during pregnancy. Results obtained conform to this belief, for blood sugar determinations were carried out on those patients who showed marked glycosuria, and normal values found in samples taken after a night's fast.

sugar reducing compounds which they contained, for in both, the concentration of such compounds was well above 50.5 mg. per 100 cc., the average of the results in the whole series. As far as could be made out, these two specimens were the only ones in which the amounts of non-sugar reducing compounds affected the reaction with Benedict's solution; results upon all other specimens could be adequately explained by the amounts of sugar which they contained.

It seems worth while to inquire into the part played by glucose and lactose in causing positive reactions in the three different groups of patients studied. The three positive tests in the control series were all due to glucose, for each specimen contained more than 40 mg. of that sugar per 100 cc. Each of the positive tests in the lactating women adequately could be explained by the amount of lactose which was present,

for in every instance this was more than 40 mg. per 100 cc. (expressed in terms of its glucose equivalent, i.e. lactose divided by 1.24).

It is somewhat more difficult to decide what sugar was responsible for the positive finding in some of the specimens from pregnant women. As has already been pointed out, an increased concentration of both glucose and lactose was present in many instances. Glucose alone might have caused a positive test more often than lactose, for 15 specimens, or three-fifths of those giving positive results, contained more than 40 mg. of glucose per 100 cc., while a similar concentration of lactose (expressed as its glucose equivalent) was present in only four of them. In six of the specimens neither sugar was present in amounts sufficiently great to give positive tests, but the sum of the two exceeded

first days after parturition. It can be demonstrated, at least in some instances, months after delivery. The lactosuria probably results from an overflow of active mammary glands.

(4) Lactose is present in small amounts in the urine of a large proportion of pregnant women. Sometimes it can be demonstrated in the early months of pregnancy, but is not always found, even in the days immediately preceding parturition. In the opinion of the Authors this lactosuria is caused by activity of the mammary glands.

(5) Glucose (fermentable sugar which is not lactose) was present in the urine of our series of lactating women in slightly greater concentration than it was in the urine of a comparable series of non-pregnant, non-lactating women, but the difference was

TABLE V  
Concentrations of sugar in urine giving negative reactions with Benedict's reagent

| Lactose.                                                          |             |                                                              |          |          |          |          |          |          |            |            |            |            |            |                    |

| Pregnant                                                          | 17          | 6                                                            | 3        | 1        | 4        | 3        | 0        | 0        | 0          | 0          | 0          | 0          | 0          | 30                 |

40 mg. per 100 cc., while in two, as already mentioned, the non-sugar reducing compounds appeared to determine the type of copper reduction test obtained. Arguing from these results, a positive test with Benedict's reagent in urine from a case of pregnancy means that glucose is probably present in amounts greater than the slight traces contained in most normal urines.

### CONCLUSIONS

- (1) A specific sensitive method for quantitatively estimating lactose in urine is described.
- (2) Lactose is usually absent from the urine of normal women, although occasionally traces, probably of alimentary origin, may be found.
- (3) Lactose is almost always present in increased amounts in the urine of lactating women during the

small and probably not significant. Sugar of this type was present in quite large amounts in the urine of pregnant women. In our series this glycosuria did not appear to be clinically significant.

(6) Positive reactions with Benedict's qualitative reagent were due to glucose in the urine from normal subjects, to lactose in the urine from lactating women, and in a majority of instances to glucose in the urine of pregnant women.

### ACKNOWLEDGMENT

Our thanks are due to Dr. F. C. Goldsborough and the staff of the obstetrical service for aid in obtaining the urines from pregnant and lactating women, and to Dr. Stuart L. Vaughan for help in carrying out the bacteriological work involved in developing the method described.

## Dry Natural Digestive Juices: Their Properties and Laboratory and Clinical Use\*

By

W. N. BOLDYREFF, M.D.

BATTLE CREEK, MICHIGAN

W. BEAUMONT was the pioneer in the study of the natural digestive juices, but it was I. P. Pavlov who made a more complete investigation. It is quite evident that the natural juices cannot be substituted by any artificial products since such preparations do not contain all the component parts of the natural juices and are besides rendered impure by various admixtures. All this may lead to serious errors, if one assumes the data obtained from artificial juices to be true of the live juices. An outstanding example of this is the assertion that the gastric juice contains lipase. Now, some of the natural digestive juices are widely used not only in every day laboratory work but for instance, gastric juice is introduced into the clinic as medicine. Moreover, during the World war an attempt was made to use gastric juice as an antiseptic for old used bandages, to clean them of pus; (Professor Leontovich, Moscow\*\*). However, the fact that digestive juices in their natural state are highly watery and they do not keep well, prevented their wide application. In the gastric juice and saliva, water content may exceed 99½ per cent. Therefore in storage and mailing, the natural digestive juices occupy much extra space, require large fragile packing vessels, adding as much weight as the juices themselves. The natural pancreatic juice, especially in its

active state is so easily decomposed due to autodigestion and presence of microbes that it can be preserved only in the frozen state which is very difficult to achieve if it is to be stored for a long period or intended for transportation. All these complications are easily avoided when one uses all the named juices in a dried state. I mean the natural dry digestive juices and not the artificial preparations, such as dry pepsin, rennin and pancreatin. These artificial substances in their present state cannot completely substitute for the liquid natural living juices any more than anything could substitute for fresh milk or egg.

The natural digestive juices, fresh and pure, are to be found in many physiological laboratories. But it is difficult to store them, they require a lot of space and vessels, are quickly spoiled, and therefore are usually thrown away after being examined or even before, when time is short. Biochemical and other laboratories and clinics not unfrequently need such juices, but they cannot always have them, for, as a matter of fact, they do not know how to obtain them from the animals. E. Fischer (Berlin) some twenty-five years ago, used to order intestinal juice from Professor I. P. Pavlov's Laboratory in Petrograd. The German scientists decided that they ought to learn to meet their own scientific needs, and sent the young doctor Nikolai (now Professor in South America) to study with I. P. Pavlov.

\*Reported March 29, 1934, at the Annual Meeting of the American Physiological Society at Columbia University, New York, N. Y. Submitted January 1, 1935.

\*\*Natural active pancreatic juice or duodenal content could do this much better and quicker.

Fig. 1. PREPARATION OF DRY PANCREATIC JUICE. I—Obtaining juice from a fistular animal. B—portion of the animal's body. A—orifice of the pancreatic fistula. The pancreatic juice flows out into a receptacle, cooled by CO<sub>2</sub>-ice, in which it immediately freezes (P). Instead of freezing and drying the juice, it could be dropped directly into some alcohol. Then the ferments would settle down in white dregs. II—Drying the frozen pancreatic juice at 0°C and 0 pressure. The juice (P) is placed into the desiccator from which the air and water vapors are pumped out with a powerful vacuum pump.

In the summer of 1907 Dr. J. H. Kellogg visited I. P. Pavlov's Laboratory in Petrograd and borrowed 20 bottles of natural gastric juice to take home to the American physicians. But during the trip the juice moulded in all 20 bottles (mould is resistant to acids) and upon his return when he found that, he had to throw it away. Nothing of the kind would happen, if the juice were in the dried state.

Quite recently Dr. P. A. Levene of this country, went over to I. P. Pavlov, too, when he needed some intestinal and pancreatic juices; it was a very complicated and almost impossible matter to obtain them from Petrograd; then Dr. Levene asked me, and for some three years I supplied him with both the intestinal and the pancreatic juice, sending them to him in frozen state in a thermos bottle. Later I rendered the same service to Dr. J. H. Northrop of the Rockefeller Institute. Other similar services I have rendered many times in Russia, Japan and this country. Requests often came unexpectedly and we had to operate on animals, if we did not have the necessary fistular dogs. All this caused many difficulties and delays in our work, and for those whom I supplied with these juices.

For this reason, as far back as thirty years ago, I tried to obtain dry preparations of gastric, pancreatic and intestinal juices, drying them with heating up to 30°-40°C in a vacuum apparatus of S. K. Dzershowski (1). However, this process had so weakened the gastric juice, due to autodigestion, that it became practically inefficient, being much weaker than the commercial pepsin or rennin. And the pancreatic juice in this process was so deteriorated that it completely lost its digestive properties. But with the intestinal juice I solved this problem successfully in 1907; drying it at a temperature of 60°-80°C, I obtained a sufficient quantity of enterokynase which I used during the six years I worked at Kazan University where I have supplied with quantities of this preparation various physiologists and biochemists who needed it. My success with the intestinal juice depended on the fact that the enterokynase, as proven by Dr. N. P. Shepoválnikov in Pavlov's Laboratory, is not destroyed even in boiling for a short time. The dry intestinal juice proved to be very convenient and the quantity filling one ordinary test tube was more than enough to serve all my own, and other peoples' needs for six years, and its properties remained unchanged during all this time. A successful experiment with kynase has incited me to attempt preparations of all other digestive juice in the dry state. This winter I was at last successful in drying all digestive juices, using a vacuum pump and drying the juices in the frozen state according to Dr. L.

F. Shackell (2)\*. One can extract from the live digestive their active principle with alcohol or draw water from them with chemically pure glycerine (thrice crystallized), but these methods are less convenient and therefore I shall not describe them although I used both of them successfully. I tested these juices for ferments before and after drying and found that drying does not affect the ferments at all. The juices were tested in the following manner. For example, I was testing the saliva, the gastric juice or the pancreatic juice for ferments content, then a certain quantity of each juice was dried to a standard weight in frozen state. One must remember that dried juices like proteins in general are very hygroscopic. Having obtained a dried juice and knowing its weight, and the volume of liquid juice it corresponds to, it is a simple matter to calculate how much liquid it would require to restore the juice to its original condition before the drying. I added some distilled water to the dry saliva, pancreatic and other juice and some 0.5 per cent HCl to the dry gastric juice. Then I tested again all the restored juices for ferments content; the results of these tests showed that the quantity of all ferments in all of them remained unchanged. Thus, the problem of preparing all digestive juices and storing them for unlimited time can be considered as solved since we know that these substances being sterile do not change when properly stored in the dried state.

Experiments with storage of dried serums have long ago shown that they do not at all lose their medicinal properties during a number of years. A similar experiment proved to me, still earlier, that even the pancreatic juice, the least resistant and most easily destroyed, preserves unchanged its digestive properties practically for ever, if stored in frozen state and not allowed to thaw.

After the first tests described above I assigned myself three problems trying to establish exactly whether drying produces any changes whatever in the frozen juices. The first problem was to see whether the dried juice can afterwards be quickly and completely dissolved without residue, so that it would be perfectly restored to liquid state without any changes in its physico-chemical condition. The test gave positive results; all dried digestive juices can be dissolved without residue very quickly, in one minute or even sooner. The second problem: do such juices preserve their physiological properties intact, do they remain live and does not their ferment action weaken with drying? As mentioned above, tests for ferment content gave positive results. The third problem: does prolonged storage during months and years harmfully affect the properties of these juices, and if it does, how much,

\*This method was kindly recommended to me by Dr. L. H. Newburgh of Univ. of Michigan.

Fig. 2. STERILIZATION AND DRYING OF JUICES (without any dessicating substance). Diagram. a—sterile porcelain filter (marked by dotted line). b—sterile cotton. c—pet-cock.

and which ones? This question cannot be answered yet—it will require several years to test it out but study of the juices which were stored during several months gives us a hope that this problem can also be solved in the positive sense. It is quite probable that preparations of hilus, blood and other semiliquid substances of animal origin made in the described manner can be stored for an indefinite, unlimited time.

As for the laboratory use of dried, live or natural digestive juices, it is truly unlimited, may be of everyday application and is well known. For this reason there is no need for a detailed discussion of it at this time.

As for the clinical use of gastric juice, it is several scores of years ago that Professor I. P. Pavlov first introduced it into medical practice and other clinicians have warmly recommended it in Europe. In one of my early papers I discussed this in detail (3).

The clinical use of the gastric juice for treatment of digestive disorders has found a wide application in Russia, France, Germany, Sweden and other countries. I trust the method of preparing dry gastric juice may help to introduce it into the clinic and into medical use in general in this country. Professor Huchard of Paris has especially favored the gastric juice; he called it "digitalis for the digestive tract." Professor I. S. Zitovich in Russia used digestive juice as an aid in weakened digestion with great benefit in consumptive patients.

The pancreatic juice. I recommend for treatment of diabetes mellitus and hemophilia. The theoretical bases for this suggestion are found in my report to the XIVth International Physiological Congress in Rome in 1932 and in XIIth International Congress in Stockholm in 1926. Details of the practical application I will soon report to the meeting of the 37th American Gastroenterological Association and several medical societies. All this material will be published shortly. The dry bile and intestinal juice will be indispensable companions of the pancreatic juice being its activators and aids in digestion, and dry saliva probably will also find its clinical application in various cases of insufficient gastric digestion which can be improved by saliva, as we know.

I recommend to use dried hilus for extreme exhaustion and malnutrition, and in distinction from other juices, taken internally by mouth, hilus can be introduced subcutaneously and in extreme cases even directly into the blood stream.

Dried juices can be added to some foods, with great benefit, when prepared in the factories. The dry gastric and pancreatic juices are especially well suited for this, but other juices can be used too. The gastric juice is best added to proteins, and the pancreatic juice to proteins, carbohydrates and fats (for instance to dry milk, etc.). Such food stuffs would be very beneficial and convenient for anemic persons, for diabetic patients, and in certain other conditions.

The process of drying is the same for all digestive juices and it is very simple. (See Figures I and II). If necessary, they are first freed from microbes and other impurities through centrifugalization and filtra-

tion through a sterile porcelain filter; after this all work is done under sterile conditions; then the juices are frozen with the aid of dry ice ( $\text{CO}_2$ -ice). Working with the pancreatic juice, especially with the active pancreatic juice, one should not lose one minute: it spoils so quickly. The frozen juice is placed into the desiccator and dried by a powerful vacuum pump at  $0^\circ\text{C}$  and the atmospheric pressure at 0. If necessary, several pumps are placed in series, in line. Some drying substance ( $\text{H}_2\text{SO}_4$ ,  $\text{P}_2\text{O}_5$  or others which would not generate any gases, vapors or hard particles which may injure the juices) is placed into the dessicator, but one may dry without it too. When dried to a constant weight the dry juice is placed into a sterile vessel, if possible of dark glass, which is hermetically sealed and kept in a dark, dry, cool place.

In the end of this work I had kind assistance of Dr. W. B. Lewis who helped me to dry some digestive juices. In our joint paper we will describe in detail the process of drying such juices, as well as their physico-chemical properties as compared to the normal juices (specific gravity, reaction, pH, viscosity, etc.).

In case the juices are contaminated by some microbes during desiccation or afterwards, a remarkable change in their appearance takes place. Then instead of a powder of a light color the dry juice is turned into a sticky black jelly. We observed this change three times at the end of the drying various samples of gastric juice and once in already dried bile, which was spoiled in transportation, having been corked with an impure cork. The main supply of the bile, from which this portion was taken, remained unchanged a powder of a brownish color.

#### TECHNICAL

Any digestive juice freshly collected and cooled (not losing one minute) should be preserved in dry state without any antiseptic material. The juice is centrifugalized and if necessary filtered through a sterile porcelain filter directly into a sterile transparent\* glass vessel which is later placed into the dessicator cooled by  $\text{CO}_2$ -ice (dry ice), when necessary. The desiccator is best of a small size (not over 6 inches in diameter\*\*). When the juice cannot be dried immediately after collection, it must be saved in frozen state

\*In order to observe the process of drying.

\*\*Because a large one may be easily crushed by atmospheric pressure (Shackell).

Fig. 3. DRY NATURAL JUICES

only. With the aid of a powerful vacuum pump (pressure not exceeding 3 m. mercury), and temperature  $0^{\circ}$  Centigrade or lower, the juice is dried to a constant weight. When necessary, to hasten the process of drying some  $H_2SO_4$ ,  $P_2O_5$ , or other sterile desiccating substances, not generating harmful gaseous vapors or hard particles, capable or destroying the ferments of the juice, may be placed into the dessicator. The drying juice should be protected from such particles from above, since they may float like dust, when there is a sudden drop in pressure in the dessicator. The dry juice is immediately placed into a narrow sterile glass vessel, the opening of which is best soldered. The dry juice should be kept in a dark cool place, free from dust. (See Fig. VI, II and III).

#### SUMMARY

When drying in the described manner any digestive juice, its ferments are not in the least affected and lose none of their digestive properties. We tested saliva, gastric, pancreatic and intestinal juices, bile, duodenal content, and also prepared dry gastric and intestinal mucus. Our juices were mostly from dogs, sometimes from human subjects. Dry juices are very quickly, almost instantly, completely dissolved in water (gastric juice in 0.5 per cent HCl). In the dissolved state they are not distinguished from corresponding natural juices. When properly preserved in a dried state without change in their properties, the digestive juices may be kept for an indefinitely long time. Small quantities of dry juices, when not hermetically sealed, must be kept in the dessicator over  $H_2SO_4$ . The dry

1. Saliva, 2. Gastric Juice, 3. Gastric Mucus, 4. Duodenal Contents, 5. Bile, 6. Intestinal Juice, 7. Intestinal Mucus, 8. Pancreatic Juice. All canine with the exception of saliva and duodenal contents, which are human.

juices are very hygroscopic and easily contaminated by microbes.

#### CONCLUSIONS

1. Any digestive juice is collected, if possible aseptically and immediately frozen in a sterile vessel with the aid of some dry ice

( $CO_2$  in solid state).

2. The frozen juice is dried in a sterile dessicator with or without a desiccating substance to a constant weight without melting. In such state it can be preserved indefinitely, almost without losing its ferment properties and without spoilage.

3. Dried juices, as also proteins in general, quickly absorb moisture from the air and then become perishable; light may be destructive also, therefore they must be kept in hermetically sealed vessels in a dark room.

4. Insufficiently dried juices may spoil either due to self-digestion (especially active pancreatic juice) or to the effect of microbes; in the second case they grow dark in color and even black and turn into a gluey mass, and their ferment properties weaken or even totally disappear.

5. Sometimes this spoilage occurs during the process of drying (particularly if it has been long in non-sterile conditions or the juices thawed) and for that reason the process of drying must be very quick\*.

\*I do not know to how low a temperature one can subject the juices without losing their ferment action. Control experiments have shown that sometimes the temperature was  $40^{\circ}C$  below zero since mercury was frozen. Further experiments are necessary in order to determine the exact low temperature and duration of freezing period harmless for live juices. However, apparently, there is no ground to fear harmful effects from low temperature.

*The Occurrence and Treatment of Neurologic Changes in Pernicious Anemia.* J. A. M. A., (December 1), 1934.

The authors present a study of a comparatively large group of pernicious anemia patients in whom there occurred neurologic and mental manifestations to determine the effect of various types of antianemic therapy on them.

Nervous system involvement has been noted in 89.2% of the four hundred and eight patients alive at the present time. Of these, 43.2% had the symptoms of cord changes at the onset of the disease and in the remainder the changes developed at some period during the course of the illness, but before the patient came under the authors' observation.

In a series of fifty of these patients especially studied, cerebral involvement occurred in 64%. The average duration of the disease in the entire group of patients before admission was about two years.

In spite of adequate antianemic therapy, improvement in symptoms of the central nervous system was observed in less than fifty per cent of the cases, and improvement in signs in about two per cent of the cases.

Antianemic therapy given in the sufficient amounts does not have a specific curative affect on spinal cord degeneration.

Genito-urinary infection, trophic ulcers and pneumonia with complicated marked central nervous system degeneration usually indicate a poor prognosis.

*A Study of Manganese Retention in Children.* Journ. Nutrit., Vol. 8, No. 10, 1934, pp. 497-502.

A manganese retention study was made on seven small children (3 to 5 years old). Three diets containing manganese varying from 0.101 mg. per kilogram of weight to 0.304 mg. per kilogram of weight were used. All three diets contained meat, milk, eggs, bananas, potato, tomato, orange juice, and cod liver oil. The low and intermediate manganese diets differed only in the choice of cereal foods; white bread and oatmeal being used in the low manganese diet, while commercial whole wheat bread and whole wheat cereal were used in the intermediate diet. Foods that are particularly high in manganese were chosen for the high manganese diet.

The result of this study was that the amount of manganese retained was found to be proportional to the amount ingested. The writers feel that manganese is essential to the physiological development of children. Since the manganese content of the more usual foods consumed by man differ widely and since some diets for children consist largely of milk and refined cereals it is possible that these diets contain too little manganese.

It is suggested that children's diets should contain from 0.20 mg. to 0.30 mg. of manganese per kilogram of weight.

*Nutritive Value of Lactose.* Journ. Nutrit., Vol. 8, Oct. 10, 1934, pp. 377-383.

A study of the nutritive value of lactose, as compared with that of sucrose and glucose, was made on full grown

rats. The rats were first fattened on a calf meal diet, then placed in small individual cages and given a diet approximately 30% to 40% below maintenance. After the rats had lost 40 grams to 50 grams body weight—lactose, glucose or sucrose was added to the diet. The rats getting the lactose diet showed a slightly greater gain over those getting the sucrose or glucose diets for the first few days. However, after the fifth to the ninth day the weight gain was distinctly less on the lactose diet. Activity was not a factor in the poorer nutritive value of lactose since the voluntary activity of rats on a lactose diet was not greater than those on a glucose or sucrose diet.

Apparently a considerable portion of lactose ingested, approximately 40% to 50% is lost to the rat as far as weight or energy relationship are concerned.

*Effect of Gelatine Feeding Upon Cases of Pseudohypertrophic Progressive Muscular Dystrophy.* Proc. Soc. Exp. Biol. and Med., 82:143-145, Nov. 10, 1934.

A study on the effect of prolonged gelatin feeding was made on three boys with well developed cases of pseudohypertrophic progressive muscular dystrophy.

Comparative results of gelatin feeding was made with that of glycine feeding. In both instances there was an increase of creatine over that of the control period. Creatine excretion on a meat free and gelatin free diet (after the gelatin feeding was over) was essentially the same as in the control period before gelatine feeding.

The investigation indicated that the general condition of the patients appeared better during the gelatin feeding. Gelatin feeding affords as much stimulation as glycine feeding in this condition, although the clinical examination of the muscles throughout the period of observation showed little changes—possibly some further degeneration.

*Pituitary Headache.* Endocrinology, 18, 5, Sept.-Oct., 1934, p. 596.

The author reviews briefly the subject of pituitary headache and reports 11 cases of which 10 occurred in women and 1 in man, an unusual occurrence. He quotes the explanation of its cause as given by the work of Doisy, Allen and Novak as being the waning of the gonad secretions at the end of the intermenstrual period, which liberates the pituitary from their checking influence and permits the gland to increase in size through over-activity. If the sella is small the hypertrophy may increase to the point of destruction of its walls, with possible involvement of the II, III, IV, V and VI cranial nerves. Cushing ascribes the pain to an increase of the intracapsular pressure of the pituitary; others, Leak, Lovenhart and Muelhberger (and more recently Adson—Proceedings of the staff Meetings of the Mayo Clinic—9, 45, Nov. 7, 1934; 673) to the irritation of the meningeal vessels. Relief was obtained promptly in all of the 11 cases by the subcutaneous injection, repeated at varying intervals, of  $\frac{1}{2}$  cc. of Infundin (B. & W. Co.). Two  $\frac{1}{2}$  grain tablets daily of pituitary posterior lobe gave less relief and the extract of the anterior lobe no relief whatsoever.

## SECTION IV—*Roentgenology*

### Cascade Stomach: A Review

By

ROY UPHAM, M.D., F.A.C.S.  
NEW YORK CITY, NEW YORK

A SURVEY of American literature on the subject of "cascade stomach" reveals scant mention of this condition. Cascade stomach has attracted far more attention in France, Italy and England than it has in this country.

#### DEFINITION

Cascade stomach is not a particular variety of "hour glass" stomach, as is considered by many, but is the result of a special change in form and position of the stomach. It has only one thing in common with hour glass stomach, that is, the division of the stomach into two parts. In cascade stomach there is a typical dilatation of the upper pocket with enlargement posteriorly into the upper posterior portion of the abdomen. It is characteristic of cascade stomach that the upper pocket is always larger than the lower pocket, and there is a distinct difference in the lumen. In hour glass stomach one pocket is situated above the other in a direct line, and there is an equal tonicity in both pockets, as well as nearly identical lumen outline. In cascade stomach the upper pocket lacks tonicity, the contents filling the upper pocket as though in a flaccid sac devoid of peristalsis. Hour glass stomach, in the lateral view under the fluoroscope, discloses but little posterior enlargement and displacement of the upper sac, and the anteroposterior diameter is a little in excess of the normal stomach; whereas, in cascade stomach there is a pronounced enlargement posteriorly of the upper sac, with the stomach far to the back of the abdomen. By a sudden change in the position of the patient the fluid contents in the toneless upper pocket can be made to change its level and a splashing is occasioned as of fluid in a cavity.

To Rieder (20) belongs the credit of first calling our attention to this condition in 1910, Assmann (1) giving him credit in his book "Die Roentgendiagnostik der Inneren Erkrankungen."

Le Wald (14) reports that he identified the condition as early as 1911 in a routine examination of some medical students at New York University and Bellevue Medical College. Le Wald termed the condition "shelf stomach."

Stierlin (23) reported the first two operations for cascade stomach in 1916. He found a callous ulcer at or near the lesser curvature with spasmodic indrawing of the greater curvature, producing deformity in each case.

Schlesinger (21) reported ten or twelve cases, finding some of the earlier instances of spasmodic cascade which disappeared with a resulting normal stomach. One of these appeared to be a reflex from duodenal ulcer, and an effort was made to parallel the condition of hour glass stomach, attention being called to the fact that there were intermittent forms in both and persistent forms in both. Schlesinger (21) endeavored to establish that intrinsic pathology might cause the condition, or that it might be a reflex from remote causes or conditions of the general nervous system.

Faulhaber (9) previously had had two cases, one of which clinically was diagnosed as gastric ulcer with hemorrhage, but at operation no ulcer was found. This case undoubtedly belongs to the type of cascade stomach which will be discussed in detail later in this article, and which is not due to intra-gastric pathology. In Faulhaber's (9) second case there was an ulcer with involvement of the pancreas, and in this case the pathology undoubtedly agrees with what is to be stressed by the writer later in this article.

Schutze (22) first distinctly reported the balloon form of the upper sac, which is characteristic of the condition. He was the first to emphasize the characteristic deformity with displacement upward of the left crus of the diaphragm, with concomitant displacement of the heart due to the dilatation of the fundus of the stomach by the fluid and gas contents. The constant upward displacement of the left crus of the diaphragm shows the excessive pressure produced by the obstruction, and at once confirms the hypothesis of a pressure-destruction of the fat in the upper left quadrant of the abdomen, further evidencing the pressure which may be exerted on the spleen, the colon, and the kidney—structures normally occupying the upper left quadrant of the abdomen. Comparing the upward pressure on the diaphragm with the hour glass, it is evident that only the nearly complete organic malignant obstruction could cause such a displacement of the left crus as is seen in nearly every case of cascade stomach. Therefore the deduction must be that the obstructive features of the cascade are of a very pronounced and obstinate character. Schutze seems to have had a particularly large experience with the condition, as he reports thirty to forty cases, and classes the deformity as dependent upon an anatomical basis.

Laurel (13) made a contribution when he drew attention to the transitory forms as differing from the true cascade stomach of pathological significance. In the course of routine methods of investigation the writer has observed the spasmodic type with a fair degree of frequency; and if the etiology of the spasmodic type is that suggested by Barclay, (2) namely, a spasm of the oblique muscle of the stomach drawing the stomach up, it can readily be understood how such a transitory cascade can occur. Laurel (13) considers this as a normal cascade form of stomach in contradistinction to the cascade form produced by a gas-filled colon, either through pressure which causes the stomach to ride above (which etiology is not complete, although it may be a partial element), or by traction of the colon. There is a cascade stomach of pathological significance; the cascade caused by gastric ulcer with cicatricial or cord formation, and cascade stomach due to malignancy.

Assmann, (1) in his work on radiographic diagnosis, agrees that gaseous distension of the splenic flexure of the colon is a significant etiological factor. In one of his cases there was marked distension of the splenic flexure of the colon, and at post mortem the stomach was found to be normal. In another case there was a diaphragmatic hernia with extreme gaseous distension of the colon, the result of tubercular peritonitis. Later, this case presented a normal stomach. In a third case of cascade stomach occurring in adhesive peritonitis, at autopsy the stomach was found to be normal.

Barclay of England, (2) in presenting the name "cup and spill" stomach in 1921, brought forward the suggestion of a spasm of the oblique muscle fibers as an etiological factor.

The cases reported by Stupel (24) all depended upon recognized pathology. His first case presented a tumor in the left hypochondrium, which was reduced by x-ray treatment, and the stomach returned to normal appearance. In his second case there was a congenital transposition of the caecum and ascending colon to the left with a chronic appendix. His third case had a diaphragmatic hernia on the right side, with upward displacement of the colon and liver.

Wilucki (27) brought out the point that extraventricular tumor in the region of the splenic flexure may act as a causal factor. He, also, was at a loss to explain the etiology, believing that spasm from gastric ulcer or reflex spasm from duodenal ulcer, or adhesions involving the stomach, could be a cause. There was also an extrinsic factor, such as gas in the colon. He particularly stresses the cicatrix of healed ulcer and the deformity of malignancy as intragastric causes.

Feissley and Fried (9) reported a case in a woman of fifty years who was operated upon twice, and still the cascade continued. At the first operation a short meso-colon was found, also a short hepatogastric ligament, and it was felt that the shortness of the ligament and adhesions about the gall-bladder explained the cascade stomach. After operation symptoms returned and two months later she was operated upon again with the same findings, except that the drawing up of the stomach was more pronounced. Neither atropin nor papaverin was of any avail. At the second laparotomy the findings were: omentum adherent to the abdominal wall, liver and surrounding structures; colon and gastro-colic ligament drawn upward. The

operation consisted of loosening the adhesions and liberating the colon and liver. A month later x-ray examination revealed that the cascade stomach was still present. The authors felt, in this case, that spasm could be excluded, as neither atropin nor papaverin had any effect. They believed aerophagy was a factor in distending the fornix of the stomach.

Webster (26) reported two cases, the first of which improved under medical treatment, and appeared to be of the spasmodic variety. His second case was one of extreme size of the two segments of the stomach, and was not affected by belladonna. At operation the stomach was found to be normal with extreme gaseous distension of the entire colon. There was a healed duodenal ulcer, and a gastroenterostomy was performed—the results not being definite. Webster also stresses the factor of spasm of the oblique muscle fibers.

Matthes (15) claims that the condition is the result of combined regional and diffuse spasticity of the stomach, and may be due to an ulcer on the lesser curvature at the seat of the spasm; that it also is encountered as the result of an enlarged spleen with gas in the splenic flexure of the colon and transverse colon, and from duodenal ulcer, and he emphasizes the fact that at times it may be due purely to spasm.

Ratkoczi (16) feels that the cascade stomach is actually a roentgenological conception, stressing that it is not a special variety of hour glass stomach. The contrast meal forms in a high-lying, bowl-shaped sac which is very much larger than the tube-shaped lower part, which later becomes filled from the upper sac, the entire meal frequently remaining for minutes before it empties into the distal part. In hour glass stomach the upper sac is usually small and the greater part of the meal flows uninterruptedly into the mostly flaccid, but at all events larger, distal part of the stomach. Various peritoneal adhesions may give rise to peculiar changes in the shape of the stomach, but never give rise to changes in size and shape such as the cascade stomach. High up, immediately below the diaphragm and more dorsally in the lower part, lies the larger bowl-shaped part of the stomach, in which the greater part of the meal gathers following ingestion. To the right, and in front, comes the hose-shaped distal part, the direction being from behind and from the left towards the right. The central part, near the pylorus, unfolds slowly, and fills with an appearance of an elephant's trunk. The fact that the lower part of the stomach lies to the right can best be seen in the lateral position. As regards the etiology, he emphasizes more the question of the distension of the splenic flexure, but claims in cases of pressure by the splenic flexure the changes must be passive ones, and feels that the entire nature of the cascade stomach is against a passive concept. The shape of the cascade stomach is too variable, and changes too quickly.

Ratkoczi (16) refers to some experiments that were carried out by Schlemmer of Budapest, in which he inflated the colon and produced a type of cascade stomach, but only in cases where there was pathology in or about the stomach, never where the stomach was normal. In taking issue with the hypothesis of dam-

ming over the tail of the pancreas, Ratkoczi (16) states that this can occur in the recumbent, but not in the standing position. This conception, it seems to the writer, is very much in error, as the deformity can be maintained readily in the filled stomach in the erect posture.

Zollschan (29) emphasizes that the typical feature of cascade stomach lies in the fact that the pars media is not in direct continuity with the pars cardiaca. He, again, draws attention to the forcing outward of the left side of the dome of the diaphragm. He stresses the cascade-like overflowing of the contents from the fundus pocket into the lower pocket, and particularly emphasizes the line over which the fluid drops. He quotes the collaborated work of Macarque and Baize, who dealt with the problem in 1926. They explained the marked bulging of the fundus posteriorly on the ground of increased pressure due to swallowing of air and stretching of the stomach wall at this point. They did not develop the possibility of the dilatation being due to displacement of other organs. Zollschan (29) reports an extensive study of the models by His, Sr. at the Berlin Anatomical Institute. It seems to the writer that the first step in the explanation is His' finding that a changed position of the spleen—a lateral displacement—is a factor which allows the fundus to become dilated. This increase of space is followed by the second factor, namely, that the stomach passes far back of the ridge at the tail of the pancreas, and that the splenic artery, running from the celiac axis outward to the spleen, lies above the tail of the pancreas and forms a further bridge upon which the posterior wall of the stomach can be obstructed by pressure. This, with the increasing area of the stomach, causes pressure necrosis of the surrounding fat, with a further drop of the stomach over the ridge formed by the splenic artery, and increased obstruction. In the case of air-swallowing there is further dilatation of the upper part of the stomach with pressure upward of the diaphragm. In two of His' models, viewed from behind, is shown some bilocularity of the stomach due to the stomach lying on the pancreas. The stomach shows a shallow, but still plainly visible, retro-pancreatic pocket, together with a fold on the posterior surface of the stomach. This was described by His, and named by him "*plica pancreatico angularis*." The factor of displacement of the spleen may be one of negative pressure in the abdomen, and, as has been noted in this article, the colon may create a similar condition by an increased positive pressure. In several cases the writer has observed the splenic flexure passing up to an abnormal position directly below the diaphragm; then, with distension, a pressure is exerted which forces the stomach backward, pushing over the upper border of the pancreas, and thus producing the obstruction to induce the cascade stomach.

At this point it seems appropriate that the particular findings in one of the cases recently seen by the writer, and verified by operation, should be mentioned. At operation the stomach was found to be perfectly normal, but the phrenico-gastric ligament was entirely absent, and the only support of the stomach was at the cardia. This, coupled with an improperly fixed spleen, allowed it to drop into a lower position, thus permitting the condition of affairs to

arise, which, in the opinion of the author, is the cause of cascade stomach—first, a factor of abnormal mobility of the fornix, which, in this case, was the absence of the phrenico-gastric ligament. This mobility permits the stomach to prolapse posteriorly and rotating on the splenic artery and the tail of the pancreas, causes the damming behind which the cup forms and the fluid cascades into the lower pocket. With the increased pressure, aerophagy becomes the routine practice of the individual with increased pressure and dilatation of the stomach in the posterior area of the fornix, where the circular muscle fibers are poorly developed. The normal stomach, being fixed posteriorly to the diaphragm and to the spleen, possesses a support that is lacking in the free fornix, and this probably is an element which prevents dilatation, but with a free, mobile fornix dilatation readily takes place.

This description explains the physical factors by which cascade stomach is acquired, and in the cases that are accompanied by pathology within the stomach, the pathology gives rise to perverted motor functions which produce a similar condition. It is possible, as before mentioned, that the colon may produce the same series of results, where, as occurred in a second case, the spleen is prolapsed and the colon extends up to the left crest of the diaphragm and is rotated in towards the median line, producing backward pressure on the upper part of the stomach, and producing the same rotation about the splenic artery and the tail of the pancreas.

Barclay, (2) in his recent book, still stresses the "cup and spill" stomach as being due to a spasm of the oblique muscle fibers. He states that he believes the possible action of this oblique muscle band may be the clue to the problem, and that if its contraction should be shown to be independent of those of the other coats, a basis would be provided for the explanation of the various forms of cascade stomach. He states that in some subjects, nearly always men, the angle over the left kidney is quite sharp, perhaps 70 degrees, so that the upper portion forms an exact cup, while the lower two-thirds of the organ drop down straight. These stomachs fill in a peculiar manner; the upper cup fills first and the food appears to spill over into the lower part, hence the name "cup-and-spill," cascade or "drain trap." The food usually comes straight forward over the brim and sometimes spills to the inner, sometimes to the outer side. The "cup-and-spill" appearance may be associated with duodenal lesions or with a gastric ulcer high up on some part of the wall. However, it does not appear to be abnormal, but a variation in normal form. Very often it is merely transitory.

Zollschan (29) dwells a good deal on the constriction of the diaphragm and the ridges which occur upon it from different development, and from the forces incident to pressure of the large fundus. One important point he brings out is that if the diaphragm is up very high, the fundus of the stomach rises much higher than normal, and that the cardia, being fixed, may become twisted upon itself and close like a valve, preventing any gas from escaping. He again stresses the necessity of an oblique view of the stomach showing that the posterior enlargement is a particular diagnostic feature of the cascade.

The French use the appellation "champagne cup" stomach because of the large sac in the upper part, the lower segment being tubular.

Brohn (4) emphasizes the pressure of the colon as the factor that produces the condition by distension and pressure, forcing the stomach backward upon the dam, but the author feels that he misses the condition of the abnormal mobility of the stomach. A further attempt has been to develop a twisting of the stomach upon its axis as a casual factor. Andre Dumont (8) states that "everything happens as if the stomach were pivoting on a transverse axis, going from the midline to the left side of the abdomen, passing in front of the vertical column a little lower than the level of the cardia. The stomach is found in front of this line, which it touches by its posterior wall, and in order to form the appearance of a cascade, it seems to swing from front to back, making a fold on its axis. In the more advanced stage the displacement of the stomach from front to back and top to bottom is increased. In the extreme stage the posterior basin becomes a true sac formed by almost the entire stomach." But, here again, there is not sufficient emphasis placed upon the fact of the probable congenital abnormality whereby the fornix of the stomach is not attached to the diaphragm.

### SYMPTOMATOLOGY

Pronounced distension and fullness with aerophagy and belching, and the characteristic feature that the patient, in most cases, is practically entirely relieved of symptoms by lying on the left side, which usually allows the upper cup of the stomach to empty. In some cases the emptying of the upper pocket is at the lesser curvature side, while in other cases it is at the greater curvature side. Sometimes the spill is over the center of the dam, but characteristic of the writer's cases has been the relief of distress on assuming the recumbent position, particularly lying on the left side.

On physical examination the characteristic findings are an abnormal prominence of the eighth, ninth and tenth ribs on the left side with an abnormal fullness of the left hypochondrium. Where the condition is pronounced, the actual distension amounts to two or three centimeters.

Absolute diagnosis, of course, is made by means of roentgen-ray examination. Because of the fact that the two pockets in some measure overlie, undoubtedly some of these cases have escaped attention, and it should be a routine practice to examine all stomachs fluoroscopically in the left lateral position. If this is done the large posterior distension of the stomach becomes evident, and the upper posterior sac can be seen extending well toward the back.

Redding (17) describes the filling by stating that if such a stomach is observed during the ingestion of the opaque meal it will be noted that the fluid collects in a wide cul-de-sac which is formed by a downward projection of the entire posterior aspect of the stomach at the level of the cardiac orifice. When this cul-de-sac is filled, the meal spills over its anterior border to canniculize the remainder of the gastric lumen. This condition, he asserts, is best demonstrated by a lateral or oblique position of the patient.

The differential diagnosis from a diverticulum of the stomach must be borne in mind, but the characteristic findings previously outlined, with the extreme size of the upper sac of the cascade stomach, will make the diagnosis apparent.

Characteristic is the level of fluid which readily can be made to splash upon agitation of the patient, and the change in shape and position on deep inspiration.

### TREATMENT

Detailed study of the treatment suggests that in the early spasmodic cases the usual anti-spasmodics may be of value. Otherwise, medically there is little that appears to be of definite value. From a review of the literature and report of the operations, the cases which have been devoid of intrinsic pathology in the stomach have been very unsatisfactory from an operative standpoint. Recurrences have taken place when adhesions were liberated, and in some instances operation has been repeated, with similar lack of success. Where the condition is spasmodic and reflex from the gall-bladder or from duodenal ulcer, attention to the exact pathology by appropriate surgical measures has brought relief from the condition; but where there is a well-defined dilatation posteriorly in a stomach that is devoid of the phrenicogastric ligament, anchoring of the upper surface of the fornix to the under surface of the diaphragm is presented as the only surgery that will overcome the posterior dilatation and extension of the upper surface of the fornix, the free movement of which allows the dropping down of the fundus behind the splenic artery and the tail of the pancreas, thus producing obstruction. Posterior gastroenterostomy, of course, is not practicable, but an anterior anastomosis with enteroenterostomy might be suggested if the superior pocket can be delineated.

As much of this pathology is due to spasm and obstruction, when the stomach is empty on the operating table, it is difficult to demonstrate the exact conditions present. As Zollschan (29) states: "It ought not to cause any surprise that all the relationships have escaped detection heretofore. Both the description and pathological anatomy fail to explain these anomalies as regards shape for the reason that only the tonus of the living organism can show the variations. During surgical intervention the tonus is changed by anesthesia." He states that proper credit must be given to the x-ray because that alone can show the condition during life, and further study by the x-ray, in conjunction with the anatomical laboratory, may deduce new anatomical facts because with the x-ray the organs are seen with their proper tone during their lifetime in their physiological, pathological relations and functions.

If these cases can be verified by a study at operation or necropsy (and we expect, with a knowledge of these hypotheses, they may be) it will establish the hypothesis that we have advanced relative to the acquired or congenital lack of the phrenico-gastric ligament with free mobility of the fundus and the ability of the

stomach to prolapse into a posterior position, where aerophagy and food stasis produce dilatation, which induces a further prolapse over the dam formed by the splenic artery and the tail of the pancreas, intensified by pressure necrosis and increased dilatation of the fundus, and obstruction at the point of damming, giving rise to the condition we recognize as cascade stomach.

Discussions of cascade stomach in the English language are very meager, and it was for that reason that the preparation of this review was prompted.

#### ACKNOWLEDGMENT

The author wishes to express his appreciation of the courtesy extended to him by Dr. Le Wald in placing at his disposal his unpublished paper and certain translations on the subject discussed in this article.

## ABSTRACTS

STEWART, W. H., AND ILLICK, H. E.

*Roentgen Diagnosis of Carcinoma at the Cardia, Am. Jour. Roentgenol.*, xxxii, July, 1934, pp. 43-51.

The authors direct attention to the relative frequency of carcinoma of the cardiac end of the stomach, they discuss methods of examining this region roentgenologically and they consider some problems in the differential diagnosis with the hope that roentgenologists will be able to assist in the early recognition of the disease. The situation of the carcinoma may make detection difficult, and this applies especially to involvement of the upper pole of the stomach. Pyloric carcinoma comprises about a half of all cases of carcinoma of the stomach, and obstructive symptoms may be prominent early. Carcinoma of the body of the stomach comprises about a third of all cases, and it generally remains undiagnosed until the condition has become inoperable. Carcinoma of the cardia is seldom diagnosed or suspected until dysphagia is present.

In the technic of roentgenologic examination of the stomach careful preparation of the patient is essential, and it is most important that the stomach be as nearly empty as possible when the examination is conducted. A

careful, preliminary roentgenoscopic examination of the chest is made to rule out the presence of lesions above the diaphragm. Examination of the esophagus is then begun by having the patient swallow a small amount of a mixture of matzoon and barium, of a creamy consistency. The patient is rotated into the right oblique position to demonstrate best the postcardiac space. The examination of the stomach is begun before the barium is given, during preliminary roentgenoscopy of the chest; the left side of the diaphragm is watched during several examinations, and the left upper quadrant is observed for any perceptible fluid level in the stomach. The real examination of the stomach, and especially of the cardiac portion, begins after the first swallow of barium enters the stomach. This barium should immediately enter the lower pole of the stomach, outlining the rugae of the midportion and collecting in a pool in the lower end; this leaves the cardiac end outlined by a gas bubble. By palpation the entire stomach is then outlined under the screen so that the pliability of the gastric wall can be tested. At this time, the gastric mucosa is studied. If organic disease is present, there is marked irregularity, an abnormal bizarre

pattern, or actual loss of relief markings, in place of the normal stripe-like appearance alternating with ribbons of barium that fill the valleys between the rugae. The patient is given about a pint of barium solution to distend the stomach fully, and is then examined at this time, between two and four hours later, and six hours later.

The ten roentgenologic signs of involvement of the cardiac end of the stomach by carcinoma are as follows: 1. Any dilatation of the lower portion of the esophagus. 2. Any abnormal retention of barium in the lower portion of the esophagus. 3. Barium passing through the esophageal orifice in a continuous stream. 4. A narrowed esophagus, and unchanging canalization through the tumor. 5. A frozen mass, infiltration preventing the normal movements of the lower portion of the esophagus. 6. A mass visible in the gas bubble, or deformation of the magenblase. 7. A mass visible after the first swallow of barium, with a distorted rugal pattern, or a mass visible after distention of the stomach by a full meal, and with contracted lumen. 8. Barium forking over the mass. 9. Gastric hypermotility. 10. Esophageal antiperistalsis.

Dysphagia is found in more than half of the cases of carcinoma at the cardia. The most common history is slight loss of weight, fatigue, belching, nausea, anorexia, and mild epigastric distress after eating; occasionally, there is real pain and vomiting. Cardiaspasm is distinguished from carcinoma of the cardia by the typically cone-shaped filling defect, with smooth margins, which is situated above the diaphragm. Greater dilatation is present than with carcinoma of the cardia, and the clinical history of the duration of the complaint is longer.

Diverticulum of the lower portion of the esophagus is rare. Varix, causing a notching of the edge of the lower esophageal outline, and masses of varices that produce characteristic filling defects of the lumen, are often difficult to differentiate.

Lesions causing outside pressure, such as those resulting from metastasis, are usually differentiated roentgenoscopically.

Hernia of the stomach through the diaphragm must also be considered in the differential diagnosis. Benign ulcer of the cardiac end of the stomach is differentiated by radial striation of the folds, the small crater, and finally by its response to medical treatment.

K. Vinson, Rochester, Minn.

H. S. SOUTTAR.

*Cancer of the esophagus, British Med. Jour., Vol. 2, Nov. 3, 1924, pp. 797-800.*

Carcinoma of the esophagus accounts for from 4 to 6 per cent of all malignant diseases. In England, the annual mortality from carcinoma of the esophagus is about 1600, 1200 of the persons who succumb to the disease being men and 400 women. Among men it is a disease of later life; 90 per cent of the patients are more than fifty years of age and far more commonly the lesions is in the lower two-thirds of the esophagus. Among women the disease may occur much earlier, and 50 per cent of the lesions are in the upper portion of the esophagus.

Histologically, carcinoma of the esophagus is almost invariably a squamous cell epithelioma and it is highly malignant.

In the majority of cases the first symptom is dysphagia, beginning with solid foods. This dysphagia usually is gradual in onset and is without remission. In a few cases in which the growth is at the lower end of the esophagus, the symptoms are rather those of flatulent dyspepsia, a feeling of fullness after meals, and eructation of gas. Pain is not an early symptom, but a reflex spasm, which results from attempts to swallow, may lead to acute discomfort. Hoarseness and aphonia may occur from involvement of one of the recurrent laryngeal nerves. Involvement

of the respiratory passages produces the most important group of secondary symptoms. Wasting occurs from starvation and the patient suffers severely from hunger and thirst.

Of the methods of examination, roentgenoscopy and esophagoscopy are described. The author is of the opinion that the passage of bougies is both useless and dangerous. Roentgenologic examination is best, as it is simple and safe. It will indicate the level of an organic obstruction and, in the majority of cases, will give indisputable evidence of the nature of the lesion. After a barium meal is swallowed and a certain quantity of it enters the stomach, the patient is placed in a high Trendelenburg position and the flow of barium from the stomach into the lower portion of the esophagus is observed. In this way, the extent of the stricture accurately can be defined.

Direct examination with the esophagoscope is undertaken to ascertain the character of the growth and the possibilities of treatment rather than for the diagnosis of a malignant stricture. Occasionally, it may be practicable to remove a fragment of growth for section, although it is not advised as a routine procedure.

The depth at which the esophagus lies, the fragile nature of its wall, the complexity of the structures by which it is surrounded, and the age at which the disease occurs, are all contraindications to surgical attack.

The main treatment of carcinoma of the esophagus consists of relief of the dysphagia which is accomplished by three methods: dilatation, intubation, and gastrostomy. Gastrostomy is usually done after failure of the other methods, although in certain cases in which the patient's condition is desperate gastrostomy is done first.

Dilatation should be attempted under the direct control of the esophagoscope. A fine, flexible bougie, on the end of a long steel wire, is passed first, and over this are passed tubular dilators of increasing size. Dilatation is usually followed by immediate relief of the dysphagia; the dysphagia, however, is likely to recur in a few weeks' time.

The author advocates intubation for malignant strictures. He has devised a flexible tube which is formed of a spiral of German silver wire with an expanded upper end and a twisted oval section that prevents upward displacement. These tubes are now in general use and are readily tolerated, the patient usually being unconscious of their presence; the large lumen permits the passage of ordinary foods. The tube is introduced with a large cone of gelatine in the end to facilitate passage through the stricture.

Cure of the disease is to be hoped for only with some form of radiation. The most direct method is insertion into the lumen of the tumor of a sound containing radium. When intubation with this spiral tube has been effected, it may be used for support of the radium. Another method is the introduction of radon seeds into the substance of the growth itself. In a few cases, a fairly satisfactory result has been obtained and the patient has recovered his power of swallowing; in no case, however, has a cure been effected.

Results of great interest recently have been obtained by Levett who used deep roentgen therapy; the rays were of short wave length and were limited to a narrow field. It is still too early to speak with any certainty of the results; in a few cases, however, it would seem that complete healing has been obtained without secondary stenosis. Another method the author is at present investigating is the application of radon to the outer surface of the esophagus after exposure by transthoracic exploration.

In conclusion, it is stated that, for the present, relief of dysphagia is regarded as the one object to aim at in treatment, and introduction of the spiral tube is the method most likely to achieve this result.

K. Vinson, Rochester, Minn.

## SECTION V—*Therapeutics*

### Therapy of Non-Malignant Biliary Tract Lesions<sup>\*</sup>

By

ALLEN O. WHIPPLE, M.D.  
NEW YORK CITY, NEW YORK

THE confusion that exists in the profession as regards the therapy of biliary tract disease is most unfortunate. There are radical surgeons who claim that all questionable gall bladders should be removed, and in the course of any upper abdominal operation, as for ulcer, excise the gall bladder as a routine. We cannot agree with this group at all in classing the gall bladder with the appendix as a vestigial pouch to be gotten rid of routinely. In addition there is a fairly large group of medical men who have a mistaken concept of the gall bladder as a nidus or focus of infection, and when every other focus, such as teeth, tonsils and sinuses, has been eliminated, pick on the gall bladder as a focus to be removed irrespective of whether it is giving symptoms or is the seat of definite inflammation. Opposed to these radicals are the conservatives, who discourage and delay surgery in the obviously diseased and chronically inflamed biliary tract until the patient, either because of unbearable repeated attacks of colic, or because of complete and unremitting common duct obstruction, develops an alarming Charcot's syndrome of chills, steeple temperature and deep jaundice, pleads for help, and the family insists upon operative relief. The writer has frequently heard the family physician stubbornly question the diagnosis of gall stones because the patient had not shown jaundice, showing his ignorance of biliary tract pathology, and exposing his general attitude toward its therapy.

The policy of delaying surgery in patients with well established and demonstrated gall bladder pathology until the inflammatory or obstructive factor has extended beyond the original site into the ducts, liver and pancreas, when urgent and unavoidable surgery carries with it a high morbidity and mortality, explains the dread of biliary surgery in the minds of the lay public as well as the medical profession. This will be demonstrated in the Tables which follow later.

There is a very safe and rational course to be followed between the unsound therapy of the extremes just mentioned. Modern accuracy in the diagnosis of biliary tract disease, and well defined therapy, now tested by many careful follow-up studies, leaves little excuse for the unsound views of the radical, or the shilly-shallying, dangerous attitude of the ignorant conservative practitioner.

In presenting our views on the therapy of biliary tract disease we wish to emphasize the rôle of the

three factors that enter into the pathogenesis of all cases of biliary tract disease requiring surgical therapy. These are (1) gall stone formation, the result of disturbed metabolism; (2) infection; and (3) obstruction. Singly or in combination, these are always present, and the part of the biliary tract where they are active determines the symptoms and physical signs. An understanding of these factors and their presence in the gall bladder or ducts makes the pathology, symptomatology, diagnosis and treatment of biliary tract disease rational, interesting, and accurate.

Based upon such an understanding we wish to present certain principles of therapy.

First, regarding the acute lesions: We believe that if the signs of acute cholecystitis do not subside promptly within 24-48 hours, under a regime of rest in bed, nothing by mouth except hot water and tea, with an ice bag to the right upper quadrant, then the gall bladder should be removed or drained. This is especially true if there is a spread of the area of right upper quadrant tenderness and muscular rigidity, indicating a beginning peri-cholecystic peritonitis. At this early stage a cholecystectomy is more feasible and the necessity of drainage with subsequent cholecystectomy is less likely. We realize that this policy is somewhat radical, and a change on our part from a conservative attitude, but our experience of the last five years in dealing with cases of acute cholecystitis bears out the opinion of many of the surgeons who have recently advocated early cholecystectomy in acute cholecystitis. The Author is certain that the relatively high mortality in the cases of acute cholecystitis in his own series was due to the earlier policy of delaying surgery until an empyema or cholangitis had made operation imperative.

As regards the chronic lesions: We believe that conservative therapy is preferable to surgery in the majority of cases of chronic cholecystitis, unless there is positive evidence in the history of biliary colic and typical interval digestive disturbances, such as bloating and belching, plus corroborative X-ray evidence of gall stones or non-visualization of the gall bladder by cholecystography. By conservative therapy we mean: 1. A careful dietary regime, excluding fried or greasy food, rich sauces, vegetables tasted after ingestion, such as cabbage and onions, fresh breads, and foods rich in lipoids and nucleo-protein with high cholesterol content. 2. Patients should be cautioned against over fatigue and especially against eating a

<sup>\*</sup>From the Department of Surgery, Columbia University.  
Submitted January 5, 1935.

heavy meal when fatigued. The findings of cholesterol crystals, calcium bilirubin particles and pus cells with bacteria in the duodenal contents obtained by duodenal intubation is, in our experience, even more reliable than cholecystography in demonstrating true pathology, that is, a lesion requiring surgical therapy. In many patients a failure of the gall bladder to take the dye or to empty it, indicates disturbed physiology of

the great majority of cases, if done while the lesion is limited to the gall bladder.

In our 62 cases of carcinoma of the gall bladder, 52 per cent have shown gall stones and chronic cholecystitis of long standing. I have never seen carcinoma of the gall bladder in an otherwise normal gall bladder. This form of malignancy is practically always fatal. Its almost invariable association with gall stones should give pause to those physicians who watch patients for years with known gall stone disease.

In the patients with inflammation or obstruction in the biliary tract beyond the gall bladder: In these cases surgery is, as a rule, urgent because of the dangers of jaundice, cholangitis, and pancreatic involvement. To delay surgical interference until the patient is deeply jaundiced, has a biliary cirrhosis, a prolonged clotting time and damaged kidneys, is

the gall bladder, but does not necessarily indicate a gall bladder requiring surgical removal.

When, however, there is strong evidence of gall stone formation or cholesterosis of the gall bladder in the work-up of the patient, cholecystectomy is the surest remedy because it removes the source of the trouble, and carries with it a low risk and a permanent cure in

negligence that might be given a significant adjective.

These cases of jaundice, damaged liver and kidneys require several days of pre-operative therapy with glucose, saline and blood infusion, and most careful post-operative care.

The value of any therapy is determined by the immediate and late results, that is, in the surgery of the biliary tract the immediate results are significant if the mortality of the operation is high or low; the late results, as determined by bona fide follow-up visits, are significant if a large majority of the patients are relieved of their symptoms.

In estimating results the writer is convinced that collected statistics are not so valuable as a smaller series of unselected consecutive cases, studied pre-

operatively, operated upon, and followed by one individual over a long period of time. For that reason I am presenting a study of 700 unselected, consecutive patients having biliary or pancreatic lesions operated upon by me during the twenty year period of 1914-1934.

Table I shows the division of these cases into the acute and chronic benign lesions, with and without stones in the gall bladder, the ducts, or both, with the mortality of the operations in each group. By mortality we mean a death in the operated patient from any cause, while the patient is in the hospital, even if the case had been transferred to the medical ward for special therapy.

Table II shows the percentage of patients followed. In this connection I would emphasize the importance of actual follow-up interviews and examinations. By this method only can accurate determinations of therapeutic results of any kind be obtained. It has been my experience that form letters or question-

naires can be very misleading, either because the patient does not wish to disappoint his surgeon or, more often, complains of symptoms under the heading of ill health, which have nothing whatsoever to do with the original system or syndrome treated.

Many of the follow-up patients continue to be air swallows after biliary tract surgery, because of a long-standing cribbing habit, and complain of belching unless they have the habit corrected before leaving the hospital. This is not a persistent symptom and should not be put down as a failure to cure gall bladder disease. It is an example of the advantage of personal interview over questionnaire method of determining therapeutic results.

Table III shows the operative results in the three main divisions of non-malignant biliary tract disease, divided into three periods of 12 months or less, 1 to 4 years, and 5 to 18 years follow-up.

## ABSTRACTS

CALLOWAY, J. LAMAR.

"Epidemic Pleurodynia." *South. Med. Journ.*, 27:1019, 1921, Dec., 1934.

Epidemic pleurodynia, ("devil's grip," "devil's clutch," or "epidemic myositis") is an acute infectious (?) disease characterized by a sudden onset of severe pain in the chest and epigastrium, particularly along the diaphragmatic attachment, accompanied by fever but presenting no significant gastrointestinal symptoms or pulmonary or pleural signs, and showing a relative leucopenia or normal white count. Improvement takes place in a few hours but recurrence is common. Either sex may be affected but the disease is more frequent in children than adults. While the disease itself is never fatal, its possibility should be borne in mind since it may simulate an acute abdomen and lead to unnecessary operation. A knowledge of the existence of an epidemic, the absence of nausea, vomiting and diarrhea, and the presence of a leucopenia should aid in differentiating these conditions. Tachycardia helps eliminate typhoid. The treatment is that of an acute pleurisy with close observation and repeated white count.

*Proteins Versus the Carbohydrates.* *J. A. M. A.*, 103: 1600 (November 24), 1934.

Food faddists have presumed that proteins and carbohydrates in the diet are incompatible because proteins require an acid medium for their digestion while carbohydrates require an alkali medium.

A study of the digestion of proteins and carbohydrates in the normal human stomach was made by the author and others some years ago. They found that the normal human stomach may be of several types. One may show a relatively slow type and another a rapid type of gastric digestion. The secretory response in these healthy subjects could also be divided into groups, some showing a tendency to a low secretory output, others to a presumed normal, and still others to a hypersecretory type of response. The most significant feature in these studies was the constancy of the type of gastric function, the individuals falling into one of these groups and maintaining his gastric type.

Food faddists point out that while the normal individual can digest practically everything, the same rules do not

apply to the chronic invalid. A group of chronic invalids, patients with nephritis, myocarditis, cholecystitis, angina pectoris, asthma, bronchiectasis and acute illnesses such as rheumatic fever and even pneumonia, were carefully studied with reference to the ability to digest protein and carbohydrate food. The studies brought out the fact that there was no incompatibility between protein and carbohydrate digestion in the human stomach, even in this type of chronic invalid.

*Free Omental Grafts—Abdominal Operations, Annals of Surgery, Vol. 100, Nov., 1934.*

1. Use thinnest and most vascular area of omentum available.
2. The graft should extend beyond the raw area to be covered.
3. The edges should be turned under.
4. Very fine catgut sutures are used and placed close together around the circumference of the graft.
5. The raw edge of the great omentum should be turned under and sutured and should not be left in a thick mass to form undesirable adhesions.
6. Resection of the entire omentum is avoided, for gastro-intestinal hemorrhage occurs in four per cent of total resection, with a mortality of fifty to sixty per cent, according to Karger of Bier's Clinic.

### CONCLUSIONS

- A. Union is complete in three days.
- B. New capillary have formed in four days.
- C. Grafts are almost completely absorbed in four months leaving the surface endothelium.
- D. Free omental grafts will live. They become adherent to the underlying attached structure, prevent adhesions to surrounding organs and at times even remain free from surface adhesions in the presence of pus.
- E. They are hemostatic.
- F. They aid in preserving peristalsis by prevention of cuppling and immobilizing adhesions.
- G. They strengthen weak suture lines and resist infection.

"Partial Gastric Fundusectomy in Treatment of Peptic Ulcer." *S., G., and O.*, 59:786-788, Nov., 1934.

Partial fundusectomy, which results in a diminution of the acid secreting surface rather than the removal of the alkaline secreting ulcer bearing area, has the further advantage of not disturbing the antro-pyloro-duodeno mechanism.

It is indicated in peptic duodenal ulcer, peptic ulcer of the jejunum after gastroenterostomy and peptic ulcer of the stomach. In the latter instance, supplemental local resection is advisable because of potential malignant

change and all cases with organic pyloric obstruction will require additional operative procedure. Following the operation, there is a marked drop in the acidity of the gastric contents, but this soon returns to approximately normal. Experimental work quoted shows a definite delay in the appearance of marginal ulcers.

The operative technique is described and seven clinical cases are tabulated. This procedure seems to have a sound physiological basis for some cases at least, and we look forward with interest to further reports by the author and others.

## SECTION VI—*Abdominal Surgery*

### Diagnosis and Treatment of Amebic Abscess of the Liver (A Study Based on 4,484 Collected and Personal Cases)

By

ALTON OCHSNER, M.D.

and

MICHAEL DeBAKEY, M.D.  
NEW ORLEANS, LOUISIANA

THE previous conception that amebic infection is a disease limited to the tropics has been invalidated by the recent epidemic, and it is now a well established fact that amebiasis occurs ubiquitously. Whereas authorities on amebiasis have for some time appreciated that the infection is prevalent in all climates, the general conception has been that the condition is limited to tropical countries. As early as 1902, Sir Leonard Rogers (1) objected to the term "tropical abscess" being used to denote the hepatic complications of amebiasis, maintaining that this complication occurred in other than tropical climates. Craig (2), in a recent collection of 49,336 cases of individuals examined in the United States, found that the incidence of positive infections with *Endameba histolytica* was 11.6 per cent. Craig (2) is of the opinion that between 5 and 10 per cent of the people of this country harbor the parasites. An erroneous conception also exists as regards the most frequent complications of amebiasis; namely, amebic hepatitis or abscess. Contrary to the general conception, amebic infections of the liver occur frequently in individuals in whom there is no clinical manifestation referable to the colon; i.e., amebic hepatitis or abscess can and frequently does occur even though there is no antecedent history of dysentery or other bowel symptoms. In a series of 52 cases reported elsewhere by us (3) there were 21 (40.3 per cent) in which a history of previous

diarrhea could not be obtained. In a group of 318 cases collected from the literature, including our own, there were 131 (41.1 per cent) in which no antecedent diarrhea had occurred. In our own series of cases, diarrhea was a symptom at the time of admission to the hospital in only 10 of the 52 cases, an incidence of 20 per cent. The relatively large number of patients with amebic hepatitis who give no history of a previous diarrhea may be accounted for on the basis of a slight amebic infection of the bowel and that limited to the right half of the colon, which would produce no diarrhea. The diarrhea encountered in amebiasis is the result of irritation and ulceration of the colon by the amebae. In those cases in which the lesion is limited to the left side of the colon, a relatively slight infection with an abnormal secretion of fluid results in frequent evacuations of watery stools. A lesion located in the right side of the colon, however, even though it may produce a similar exudation of fluid into the colon, is not associated with diarrhea because the fluid is absorbed in its passage to and through the uninvolved and normally functioning left side of the colon. Rogers (4) found in 13 of 36 autopsied cases that amebic ulcers were limited to the cecum and that in 4 more they extended only as far as the ascending colon. In nearly half the cases only the proximal fourth of the large bowel was involved. In 6 additional cases scars were found in the cecum and the ascending colon. Thus, in 23 of 36 cases, almost two-thirds, the lesion was limited to the cecum and

\*From the Departments of Surgery, Tulane University School of Medicine, Charity Hospital and Touro Infirmary, New Orleans.  
Submitted December 17, 1934.

ascending colon, indicating that during life the amebic infection was latent. This observation confirms the above statement that the absence of diarrhea in no way excludes an amebic infection of the colon.

### DIAGNOSIS

Amebic hepatitis should always be considered in a patient with a persistent enlargement of the liver associated with pyrexia. A history of previous diarrhea is confirmatory evidence, but the absence of such a history in no way eliminates the possibility of amebiasis. The presence of pain and tenderness in the right upper quadrant, especially limited to the liver or radiating to the right shoulder, is corroborative. Associated with these findings there is usually a moderate leucocytosis without concomitant proportionate increase in the polymorphonuclear leucocytes. Pain was the most prominent symptom encountered in our own series of cases, being present in 80 per cent of instances. Tenderness along the right costal margin was present in the same incidence. In our series the average white blood count was 14,000 and the polymorphonuclear leucocyte count 79 per cent. Rogers (1, 2, and 5) and Manson-Bahr and Willoughby (6) have emphasized that in amebic hepatic abscess there is a moderate increase in leucocytes as contrasted with the marked leucocytosis which is seen in bacterial hepatitis and abscess.

One of the most important reliable aids in the diagnosis of liver abscess is roentgenography. According to Granger (7) characteristic changes in the contour of the diaphragm are found in liver abscess and subphrenic infections. In uncomplicated liver abscess there is distinct bulging of the diaphragm and pointing upward into the lower lung field, which is almost pathognomonic of liver abscess. In a case with liver abscess complicated by a subphrenic abscess in addition to the elevation of the diaphragm there is an obliteration of the cardiophrenic angle in the anterior-posterior roentgenogram (Fig. 1) and obliteration of the anterior costophrenic angle in the lateral view (Fig. 2), whereas in subphrenic abscess originating in other lesions there is obliteration of the costophrenic angle in the anterior-posterior view and obliteration of the posterior costophrenic angle in the lateral roentgenogram. Pancoast (8), Dickinson (9), and Love (10) emphasize the importance of elevation and immobility of the diaphragm in amebic abscess of the liver. These authors stress the importance of fluoroscopy and examination of the patient in the upright position when such is possible. We have been able to corroborate Pancoast's (8) finding that lung reactions in subphrenic lesions are of importance when present and usually indicate an amebic infection, because these abscesses are most frequently found on the convex surface of the liver in close contact with the diaphragm. The value of x-ray in the diagnosis of amebic hepatic abscess is well exemplified in the series of cases reported elsewhere by us (3). In 57 cases in which x-rays were made diagnosis was positive in 50 (87.7 per cent).

If, in addition to the above mentioned positive findings, one finds in a careful examination of the stools either active amebae or encysted forms, a positive diagnosis of amebic hepatitis can be made. Here again, however, a negative finding does not eliminate amebiasis as a cause of liver involvement.

The diagnosis of amebic abscess of the liver can be definitely established by aspirating the typical "chocolate-sauce" pus from the liver. We agree with Constantini (11), Chen et al (12), and Manson-Bahr (13) that the obtaining of the chocolate-sauce pus on exploratory aspiration is pathognomonic of amebic abscess of the liver. Because of the danger of a secondary infection of an amebic abscess and because one can never definitely rule out a pyogenic abscess, it is important that exploratory aspiration be performed in such a way that a contamination of an uninvolved serous cavity not be done. We cannot agree with Young (14) that the danger of infecting the pleural or peritoneal cavity by aspiration has been overemphasized and are inclined to believe that Young is fortunate in being able to base his opinion upon observations made in uncomplicated amebic abscess. It is also imperative that the aspiration be done in the operating room so that if pyogenic microorganisms are found in the aspirated material, an immediate open drainage can be performed. In order to determine the presence or absence of pyogenic organisms a smear should be made immediately after aspiration and if a large number of such organisms are found, open drainage should be instituted. In those abscesses located posteriorly, it is important that the needle be introduced below the costophrenic angle and inserted upward into the abscess cavity. Under no circumstances should the pleural cavity be traversed, even though many are of the opinion that this precaution is not justified, because uncomplicated amebic abscesses are sterile. Ludlow (15) stresses the fact that in aspirating amebic abscess of the liver, the needle should not be introduced more than three to four inches because of the danger of injuring a large vessel. It is occasionally necessary to attempt multiple punctures before pus is encountered. If such is done, it is important to remove the needle entirely before introducing it rather than changing the direction of the needle at the original site in order to obviate extensive injury to the liver.

### TREATMENT

The majority of amebic abscesses of the liver are sterile. In 46 cases reported elsewhere by us (3) in which a statement was made concerning the bacteriologic examination of the pus obtained from the abscess, the pus was found to be sterile in 41 (89 per cent). In a series of 386 collected and personal cases there were 328 (83.9 per cent) in which the pus was sterile. As a large proportion of amebic abscesses of the liver are sterile, the avoidance of secondary infection by open drainage is imperative similarly as in non-infected tuberculous abscesses. As emphasized in our publication elsewhere (3), the prognosis in amebic abscess of the liver depends to a great extent upon the secondary infection of the abscess cavity and the type of treatment employed. Rogers (16) showed that the mortality rate of 56.8 per cent which was obtained in cases with open drainage was decreased to 14 per cent in those cases in which closed drainage was used. The value of closed drainage is shown in Chatterji's (17) series in which there was a mortality rate of 1.6 per cent. The greater mortality rate in those cases treated by open drainage was due undoubtedly to the secondary infection of the abscess cavity from which there is considerable absorption and extension of the

Fig. 1. Anterior-posterior roentgenogram of chest and diaphragm in amebic abscess of the liver (Case report). Note characteristic elevation of right leaf of diaphragm and obliteration of cardiophrenic angle.

The technic of aspiration depends considerably upon the clinical manifestations. In those cases in which there are localizing signs and pointing of the abscess, the aspirating needle should be introduced directly over the mass. Otherwise, the aspirating needle should be introduced in such a way that the pleural and peritoneal cavities are not traversed, which can be best accomplished by introducing the needle in the ninth intercostal space in the anterior axillary line and directing it upward, medially, and backward. Occasionally an abscess can be entered by introducing the needle below the twelfth rib and extending it upward and anteriorly. After pus has been obtained by means of the aspirating needle, it is frequently necessary to introduce a trocar in order to evacuate the abscess contents completely because of the thickness of the pus. Kilner (21) emphasizes that frequently the thick contents of the abscess will cause blockage of even a trocar, giving a false impression that the abscess has been evacuated. When the abscess cavity has been evacuated of its contents, it is neither necessary nor desirable to introduce any substance into the abscess cavity, as it has been shown by Rogers (5), Talbot (22), and Chatterji (23) that the use of irrigating solutions and amebicides is valueless. If an immediate smear of the abscess contents shows the presence of a large number of pyogenic micro-organisms, open drainage of the abscess should be done because of the secondary infection; otherwise, open drainage is definitely contraindicated.

Immediately after aspiration of the pus from the abscess, an intramuscular injection of emetine should be given, because following the release of tension within the abscess, according to Rogers (5) and Talbot (22), there occurs an exudation of lymph, containing the injected emetine, into the abscess. Emetine is administered in grain doses daily until from 6 to 10 (grams 0.39 to 0.65) grains have been given. According to Leake (24), emetine administered over any given period of time should not exceed 10 mg. per kilogram of body weight. The maximum dose for a patient weighing one hundred and fifty pounds would be approximately 10 grains. Emetine should be used cautiously, because as shown by Rinehart and Anderson (25), working in Leake's laboratory, it produces in the experimental animal severe injury to the cardiac muscle. Leake (26) is of the opinion that although the other amebicides, acetarsone, carbarsone, treparsol, chiniofon, and vioform are safer and more efficient in the treatment of intestinal amebiasis, they should not be used in amebic hepatitis and liver abscess, as they themselves are toxic to the liver.

#### CASE REPORT

A. S.: Admitted to a Medical Service, Charity Hospital, New Orleans, La., on 9/24/34 with a diagnosis of phthisis pulmonis.

White male—Age 53 years—Fisherman

C. C.: Pain in upper right quadrant of abdomen.

P. I.: Began to suffer from pain in upper right quadrant eleven weeks ago. Pain cramp-like in character, located just below costal margin. Has had this pain off and on for past eleven weeks. No pain on respiration. No

process into contiguous portions of the liver. Only by keeping the abscess cavity closed is there any possibility of maintaining the sterility of its contents. Secondary infection occurs following open drainage in spite of meticulous care being used to prevent contamination. The advantage of aspiration of the abscess combined with emetine therapy has been emphasized by many investigators (Manson-Bahr et al (18), Thurston (19), and Ludlow (20)). We have been able to collect 4,035 cases, including 46 of our own, in which open operation had been performed. In this group there were 1,908 deaths, a mortality rate of 47.2 per cent. We have also collected 459 cases, including 24 of our own, treated by conservative measures; i.e., closed drainage and the administration of amebicides. There were 32 deaths, a mortality rate of 6.9 per cent. These figures illustrate graphically the advantage of the conservative treatment over the open drainage of amebic liver abscess. In our own series there were 46 patients in which an open operation was done with 9 fatalities, a mortality rate of 19.5 per cent, which indeed compares favorably with the mortality rate obtained from the collected cases in which open operation was done; i.e., 47.2 per cent. There were 24 cases in which the conservative treatment was used with 1 death, a mortality rate of 4.1 per cent. Every case of suspected amebic abscess should be given the advantage of a course of emetine therapy before any other procedure is used unless there is apparently danger of rupture of the abscess. Emetine in 1 grain doses (gm. 0.065) should be given daily for from two to four days before aspiration. Frequently in small abscesses no other therapy will be necessary. In the majority of instances, however, emetine will not suffice and some measure will be necessary to evacuate the abscess contents. After the preliminary emetine treatment aspiration of the liver should be done preferably under local analgesia. Occasionally, however, difficulty is encountered in locating the abscess. A general anesthetic might be used, but is seldom necessary.

Fig. 2. Lateral roentgenogram of chest and diaphragm in amebic abscess of the liver (Case report). Note characteristic elevation of diaphragm and obliteration of costophrenic angle.

chest pain, cough, hemoptysis, or night sweats. No nausea or vomiting. Is constipated; stools dark brown, no blood.

*P. H.*: Dysentery for twelve years, which stopped in 1928; undetermined in type. Eight years ago abscess of undetermined origin in upper right abdominal quadrant which was drained by aspiration but no anti-amebic therapy.

*F. H.*: Father and mother dead, age and cause unknown. Married. Wife and nine children living and in good health.

*S. H.*: Fisherman by trade. Drinks considerable amount of coffee and smokes a great deal. Moderate imbibition of alcoholic beverages.

*P. E.*: Patient is elderly white male, fairly well developed, but poorly nourished. Skin: Warm, moist, elastic, no eruptions or pigmentation. Pulse good, 80 per minute, with slight evidence of sclerosis. Respiration normal. Blood pressure 108/66. Temperature 101.4 degrees F. Right side of chest appears more prominent posteriorly than left, and there is slight lagging on respiration and slight diminution of breath sounds in this area. No rales or friction rubs or tactile fremitus. Liver dullness is slightly higher than normal. On examination of abdomen there is tenderness on palpation over the liver in the upper right quadrant and over the right twelfth rib posteriorly. Liver is enlarged two finger breadths downward. Spleen is not enlarged.

#### Laboratory Examination:

*Urinalysis*: Negative.

*Blood examination*:

|                    |           |
|--------------------|-----------|
| Total R.B.C.       | 4,275,000 |
| Total W.B.C.       | 8,750     |
| Hemoglobin         | 65%       |
| Small mononuclears | 10%       |
| Large mononuclears | 2%        |
| Neutrophils        | 88%       |

*Examination of Feces*: No ova, cysts, or parasites.

*Wassermann*: Negative.

*X-ray examination*: Views of chest show definite elevation of right leaf of diaphragm with obliteration of cardiophrenic angle in AP. view and anterior costophrenic angle in the lateral view (Figs. 1 and 2).

On 9/26/34 thoracentesis was done, and thick, creamy pus obtained, which was sent to the P.D. Report on this was: Smear—No organisms; culture—No growth.

On 10/2/34 consultation with surgery.

Diagnosis: Amebic abscess of the liver. Transfer to Surgical Service.

On 10/4/34 patient was taken to operating room. Under local novocaine analgesia a fairly large aspirating needle was inserted in the anterior axillary line just below the costal margin upward, posteriorly, and medially. A large abscess cavity was entered and 270 cc. of typical chocolate-sauce pus was removed. A smear was made at the time and no motile ameba or evidence of secondary infection found. The specimen sent to the Pathology Department showed no organisms and no growths.

On 10/5/34 patient was given 2 grains emetine hydrochloride; 2 grains on 10/6; 1 grain on 10/7; 1 grain on 10/8; 1 grain on 10/9; 1 grain on 10/10; 1 grain on 10/11; and 1 grain on 10/12/34.

Temperature was 101.4 degrees F. on admission and varied between normal and 100 degrees F. and 101 degrees F. until emetine and aspiration therapy were begun. The following day the temperature rose to 99.4 degrees

F., but after that remained normal until discharged on 10/16/34.

#### SUMMARY AND CONCLUSIONS

1. Amebic infection of the bowel and an associated amebic abscess occur much more frequently than is generally supposed and are not limited to tropical countries.

2. Amebic hepatitis and abscess occur without an antecedent history of diarrhea.

3. Pain and tenderness along the right costal margin accompanied by fever and unexplained liver enlargement are suggestive of amebic hepatitis and abscess.

4. Characteristic x-ray findings are of importance in the diagnosis of amebic abscess of the liver. The aspiration of the chocolate brown sauce pus from the liver is pathognomonic of amebic hepatic abscess.

5. As a large proportion of amebic abscesses of the liver are sterile aspiration of the abscess contents combined with the subcutaneous administration of emetine is the best method of treatment. Open drainage is indicated only in those relatively few cases in which secondary infection of the abscesses occurred. Precaution should always be taken to prevent contamination of uninvolved serous cavities. The prognosis in amebic abscess is good in those cases in which the abscess is sterile and in which closed drainage is used.

6. In a collected series of 459 cases, including 24 of the authors' own, treated by closed drainage the mortality rate was 6.9 per cent as contrasted with a series of 4,035 collected series, including 46 of the authors' own, the mortality rate was 47.2 per cent. In the authors' cases in which open operation was done a mortality rate of 19.5 per cent was obtained, whereas in 24 cases in which conservative treatment was used there was a mortality rate of 4.1 per cent.

7. A typical case of amebic abscess of the liver is reported.

## ABSTRACTS

THOMAS M. JOYCE, M.D.

*Tumors of the Small Intestines, Annals of Surgery.*  
Vol. 100, Nov., 1934, No. 5.

Dr. Joyce calls attention to the fact that relatively few tumors of the small intestines are diagnosed before operation. Raiford in a review of a series of 88 small intestinal tumors found the incidence of malignancy to be 43 per cent.

Carcinoma of the small bowel is usually of the annular type with a tendency to constriction, readily adherent to adjacent structures. On malignant degeneration of a small papilloma such a growth is quite massive yet causes no obstruction of the small bowel.

The benign growths are usually intraluminary, freely movable, non-adherent externally, with a tendency to intussusception.

The most common location for carcinoma of the small bowel is the duodenum and then the jejunum. The ileum shows the lowest incidence of carcinoma and the highest incidence of tumors of the lymphoblastoma group.

Many so-called lymphoblastomas eventually turn out to be on a chronic inflammatory basis. The majority of benign tumors are adenomata and may occur in any place in the small bowel—the greatest frequency is the ileum, next duodenum and last in the jejunum.

**SYMPTOMS:** 1. The picture is generally that of an obstruction—usually a partial intermittent affair. Except in intussusception do we have the picture of complete obstruction. Intussusception is a complication of about 30 per cent of all small intestinal tumors.

2. Hemorrhage, either gross or microscopical.

3. Pain due to obstruction present.

4. The presence of a mass palpable at any time, probably the most important physical sign to be looked for. It may not be constant as in intermittent intussusception. One important characteristic is their mobility.

The presence of unexplained gastro-intestinal hemorrhage, intermittent obstruction or a history not typical of any other common abdominal condition should draw attention to the possibility of a tumor of the small intestines.

The x-ray examination is of great importance in establishing the pre-operative diagnosis of these lesions, especially in showing distended loops of small bowel evidencing obstruction.

Charles T. Sturgeon, M.D., Los Angeles.

STANTON, E. MACD.

*Acute Appendicitis. S., G., and O.*, 59:738, 1934.  
1934.

The author reports a series of 1004 cases of acute appendicitis, covering the period from 1907 to 1934. Analysis of these cases emphasizes two fundamental truths:

1st: The operative mortality of acute appendicitis bears a definite relationship to the acute inflammatory processes prior to the time of operation. For practical purposes the duration can be measured in terms of the day of the disease on which the patient is operated upon. Mortality after operations, during the first 24 hours of the attack, is about 1 per cent. Average mortality during the second day of attack is from 2 to 3 per cent. After about 40 hours, the rate tends to rise sharply, so that in cases in which the operation is done on the third day of the attack, the operative mortality averages about 10 per cent. Fourth or fifth day operations are even more dangerous than third day operations. Beginning with the sixth day, operative mortality starts to decline, and by the ninth or tenth day it again corresponds approximately with second day cases.

2nd: Mortality rate is observed from day to day in this disease is inseparably associated with the corresponding sequence of changes in the inflammatory process itself, in both the appendicitis and the complicating peritoneal lesion. By the third day the intra-peritoneal exudate is of a distinctly purulent character. There is, as yet, little or no evidence of the formation of sharply defined abscess cavities. Patient has not developed any considerable immunity to the infection. By the sixth day, definitely defined abscess cavity begins to be formed with development of relative immunity against the infection.

K. Hosoi, New Orleans.

COLLER, F. A., AND POTTER, E. B.

*The Treatment of Peritonitis Associated With Appendicitis. J. A. M. A. 103:1753 (Dec. 9), 1934.*

This paper deals with a study of 336 patients with acute appendicitis. There were 213 cases in which the disease was limited to the appendix or its immediate vicinity. There was only one death in this group, a mortality rate of 0.46 per cent. The second group consisted of eighty-five patients. In these patients the diagnosis of a diffusing peritonitis was made. Eight patients of this group died giving a mortality rate of 9.4 per cent.

The third group comprised thirty-five patients. A definite diagnosis of appendiceal abscess could be made in all of these cases. Two patients died in this group, a mortality rate of 5.7 per cent.

A fourth group of three children admitted to the hospital in a moribund state are included in the mortality statistics of the entire study.

It is with the group of eighty-five patients whom the authors are particularly interested. They emphasize that the diagnosis of a diffusing peritonitis is not easy. They stress the Hippocratic "facies," dehydration from vomiting fever often up to 104F, rapid pulse and respiration rates, restlessness and a rigid diffusely tender abdomen and a high leucocytosis. The treatment they have used in this group consists of Fowler's position, heat to the abdomen, and morphine in sufficient quantities to keep the patient free from pain and apprehension. The stomach is emptied by siphonage. Nothing is given by mouth. Physiologic solution of sodium chloride and 5 per cent dextrose solution are given alternately by continuous intravenous drip, at least 5000 cc. is given daily to an adult. The urine and blood chemistry are studied. No enemas are given.

The authors feel that this deferred operation method of treating cases of appendicitis with diffusing peritonitis is of definite value.

Francis D. Murphy, Milwaukee, Wis.

GILE, JOHN F., AND BOWLER, JOHN P.

*The Management of Perforated Appendicitis. J. A. M. A. 103:1750 (Dec. 8), 1934.*

The authors present a series of 901 cases of appendicitis. The discussion is concerned with the handling of cases of perforated appendicitis which they classify into three types, group one, gangrenous appendicitis with local peritonitis; group two, appendiceal abscess; and group three, perforation with general peritonitis.

The authors are convinced that immediate operation in early peritonitis has prevented the development of diffuse peritonitis in some of these cases. They feel that appendiceal abscess represents a localized process from the very start and presents no emergency needs. They stress that late general peritonitis involves an enormous mortality.

They emphasize early observation, early diagnosis, and early operation.

Francis D. Murphy, Milwaukee, Wis.

DIXON, CLYDE F.

*Carcinoma of the Cecum: What Are the Chances for Cure? J. A. M. A., 103:1605 (November 24, 1931).*

The author reviews one hundred and forty-five patients of cancer of the cecum where resection was performed. Of these one hundred and forty-five patients, sixty have lived for five years or longer following resection. The outstanding features in regard to these sixty cases were: the patients had lost weight markedly; they had a secondary anemia; and a mass could be palpated in the right lower abdominal quadrant. Obstruction is a variable symptom in cases of carcinoma of the cecum.

The duration of the symptoms varied from a few weeks to many years.

Involvement of the lymph nodes was found in fifteen of the sixty cases. The posterior wall of the cecum was the most common site of the malignant growths.

The surgical treatment of carcinoma of the cecum consists of radical removal. Some surgeons perform the operation in one stage, others prefer to do an ileocolotomy. If the patient's condition is good, a one stage resection may be done. Anastomosis has to be performed between the ileum and the transverse colon.

The preparation of patients for operation is very important. They are given a diet of 2,800 calories a day, of foods of lowest residue, principally carbohydrates, such as fruit juices, candies, custards, gelatin, rice, eggs, thin soups and broths.

Francis D. Murphy, Milwaukee, Wis.

R. E. CHURCH AND J. W. HINTON.

*A Study of 671 cases of peptic ulcer with special emphasis on 114 post-operated cases. N. Y. State Journ. of Medicine, 34:24, 1079 to 11084, Dec. 15, 1934.*

From the Gastro-Enterological Clinic of the Fourth Medical and Surgical Divisions at Bellevue Hospital, Church and Hinton report 671 cases of peptic ulcer in six years. Of these 164 had already been operated upon. Of the remaining 507 surgery was found necessary in 46. Before considering surgery each patient was submitted to a strict medical regime. Perforation and severe hemorrhage each occurred fifteen times. By patient persistence with the medical treatment, the authors find that very few ulcers cause organic obstruction, and that the real indication for operation is severe pain unrelieved by medication or diet. The cause of such pain is probably pancreatic.

The authors have reviewed 114 operations in 103 chronic ulcer patients, excluding 81 cases of perforation. There were 92 males and 9 females, 78 of them being between the ages of 20 and 50, and four above 60. Of occupation the largest group, 14, were chauffeurs, truckmen and automobile mechanics, while 13 were clerks, ticket agents, cashiers and teachers and 6 were housewives.

The answers to the question: Why was the patient subjected to surgery? were: (1) Uncontrollable pain in 85, (2) Obstruction associated with pain in 10, (3) Bleeding associated with pain in 8, (4) Obstruction alone in 4, and (5) Obstruction with bleeding in one. There were 85 gastroenterostomies, 11 resections, 7 pyloroplasties, 5 simple excisions and 3 dissociations of old gastroenterostomies. Eleven of the series had preoperative hemorrhage and 12 postoperative hemorrhage.

Following 96 short-circuiting operations, there were 16 marginal ulcers, or 16.7 per cent. These operations were all done in the vicinity of New York City and no one surgeon performed any two operations. The marginal ulcer cases followed to a great extent the same course as an original ulcer case and were treated by the same medical regime. Operation was done only when pain could not be relieved. The end results in 106 surgical cases were 39 cured, 13 benefited and 55 unimproved. Of the last group sixteen have developed marginal ulcers. Thirteen patients who obtained complete relief from their symptoms through operation, eventually had severe recurrences, six of them over five years after operation, and one twelve years after operation. The authors conclude that present methods of treatment, whether medical or surgical, do not give a hopeful outlook for ulcer patients.

Walter A. Bastedo, New York City, N. Y.

## SECTION VII—*Surgery of the Lower Colon and Rectum*

### Pruritis Ani—A New Treatment

By

NATHAN J. SIMMONS, M.D.  
BOSTON, MASSACHUSETTS

**P**RURITIS ani is one of the most troublesome affections encountered in rectal surgery. It is characterized by persistent intense itching in the anogluteal region. Physicians often belittle the manifestation and dismiss the patient with a smile and a salve.

Gant (1) has listed over one hundred causative factors. The methods of combatting this condition are probably twice as long.

The first and frequently only point on which there is any general agreement in respect to the problem of treating pruritis ani is this: Try to remove the cause.

The only pathologic changes seen on examination may be pleats and folds in the perianal skin. There are two varieties, the dry and the moist. The first is characterized by a thickened, indurated skin, while the second presents an excoriated and macerated appearance with bleeding points.

My classification as to the etiology of pruritis ani is:

I. Pathological changes in or about the rectum and anus, such as colitis, proctitis, fissures, fistulae, hemorrhoids, cryptitis and papillitis, ulcers, skin tags, tumors of the rectum, and mucous polyps.

Montague (2) in 349 cases reported that 67% of local rectal pathology was the causative factor of pruritis ani. Frequently colitis or proctitis are the underlying causes.

Jameson, (3) Albright, (4), and Decker (5) describe red lines seen in some cases under the perianal skin which, they maintain, are channels draining an acid secretion from an inflamed mucosa and irritating the skin. These cases might respond to the treatment of repeated injections into the mucosa of quinine-uric acid hydrochloride (5%) or phenol in oil (10%). The solution causes an inflammatory fibrosis and seals off the channels from the discharge. Irrigation of the rectum and regulation of the diet may help to allay the inflammation of the mucosa. Fissures and fistulae by their irritating discharges may also incite itching and, therefore, should be eradicated.

Internal hemorrhoids, although they are not the greatest cause of pruritis ani, should be removed or treated by the injection method when present.

II. Infections of the skin or mucous membrane

a. Bacterial infections

Murry (6) took cultures from the itching areas and found that the streptococcus fecalis was quite predominant. A vaccine was made up of this material, and 168 patients were treated with only 13 failures.

Twelve to twenty injections were given to each patient. One hundred seventy-five million to one billion killed organisms were given at each dose.

Knowles (7) and Carson (8) also reported good results with this treatment but occasionally had to add the colon bacilli. The vaccine supposedly was given to raise the opsonic index which is said to be below normal in these cases. Non-specific therapy may be responsible for the relief of the itching rather than the specific form of therapy.

Montague (2) on his own investigation found the staphylococcus albus and colon bacillus where the epidermis was injured by traumatization or maceration. He treated a few cases by injection of a vaccine made of this culture but obtained poor results.

Bassler (9) and Connors (10) used an autogenous vaccine twice a week made of streptococcus fecalis, and gradually increased the dosage until reaction was obtained. They reported very favorable results. The injections were given subcutaneously.

b. Fungi and mycotic organisms

The epidermophyton, trichophyton, yeast, and molds have been recovered from scrapings taken from the itching perianal skin. Tests were performed by soaking the scraped scales in 25% potassium hydroxide and examining them under the microscope. These organisms cause some skin changes. Treatment should consist of a suitable fungicide.

c. Scabies and pediculosis

These two conditions are apt to go undiscovered when not thought of.

d. Trichomonas vaginalis may cause intense itching about the anus. It is wise to examine, and if present, treat that condition by carbasone suppositories, Lassar's paste, or sodium perborate douches. A heavy leukorrhea may cause sufficient irritation to start the patient scratching, cause infection, and beginning of a pruritis ani. It can be corrected by proper attention.

III. Systemic diseases causing peri-rectal itching

a. Diabetes

b. Liver disease

c. Anemia, exophthalmic goiter, menopause, pregnancy

d. Worms, especially pin worms in children

e. Genito-urinary diseases, causing itching reflexly

f. Food allergy—sensitization

g. Syphilis

h. Neurosis

#### IV. Idiopathic or Essential pruritis ani

We must eliminate all known causes before we are justified in classifying a case as essential or idiopathic. It is in this group that treatment of various sorts have been particularly numerous. Treatment in this group is divided into the following: Hygienic, dietetic, and local.

The physician must stress cleanliness of the anal region particularly after defecation. The parts about the anus often respond to a lysol washing 1:80. The success of this treatment speaks for a non-specific infection. The patient must be cautioned against scratching and infecting himself. Night covering should be light and warm. Wool blankets should not be next to the patient. Keep the sleeping room at a cool temperature. A good quality cleansing tissue or toilet tissue should be used. Frequent bathing and thorough drying with an application of dusting powder will allay the irritation.

The diet should consist of bland foods. Avoid hot, rich, or sweet foods, and condiments. Care should be taken that neither constipation nor a fluid bowel movement occur.

Local treatment consists largely of local subcutaneous injections of anesthetics or alcohol and applications of antiseptics. A great variety of preparations have been used.

Hopfinger (11) treated 11 stubborn cases of pruritis with diathermy. He reports 8 cures, 2 partial cures, and 1 failure. Contraindications to this treatment are eczematous or pyogenic lesions in the skin.

I have injected  $\frac{1}{4}$  to  $\frac{1}{2}\%$  of quinine-urea hydrochloride subcutaneously about the itching area. As much as 20 to 40 c.c. may be used at one time, but the injection causes a great deal of pain. I preceded it by  $\frac{1}{2}$  to 1% procaine solution to ease this pain. Anesthesia is obtained for about two to four weeks.

Hanes (12) advocates subcutaneous injections of dilute hydrochloric acid in 1:5000 or 1:2000 preceded by 15 to 30 c.c. of  $\frac{1}{2}\%$  novocaine solution perianally or morphine sulphate subcutaneously for pain. Fifteen to twenty c.c. of the dilute hydrochloric acid are injected and repeated at weekly intervals for about four treatments. His theory is that the acid kills the organism or causes its environment to be uninhabitable. It does not destroy the nerve endings. It causes an influx of blood to the drained tissues. Leukocytes are increased. Hospitalization for one-half to one day is best for patients who undergo this treatment.

Stone (13) uses 95% grain alcohol. It is painful if not preceded by novocaine. He measures off squares one-fourth of an inch apart about the anus, plunges a very fine needle through the skin into the subcutaneous tissue, and deposits two to four drops in each square. He reports excellent results. Itching is abolished at once; numbness develops just as in an operative procedure. Injections are repeated as often as one desires. Anesthesia and relief from pruritis may persist for six months to a year. His cases must have at least eight to ten treatments.

Buie (14) hospitalizes his cases and injects 20 to 40 c.c. of alcohol subcutaneously at one time. Sloughs appear quite frequently but heal in time.

Goldbacker (15) uses 5% phenol in oil and injects it subcutaneously about the itching area.

Gabriel (16) uses a solution called A. B. A., a mixture of anesthesine (5%), benzyl-alcohol (10%), and

phenol (1%) in 5 c.c. of sterile oil and obtains very favorable results. I have used this, but I find that it causes a great deal of pain. Anesthesia is prolonged three to six months in some cases.

Yeoman (17) and his associates use benacol solution. It is only slightly anesthetic to the peripheral nerve endings. Anesthesia lasts for about two weeks.

Tashjian (18) has been able to mobilize histiocytes about itching areas by injections of sterile broth solution, triple distilled water, or hemoglobin. He claims these histiocytes have phagocytic tendency and destroy the prevailing infection. The nutrient broth consists of 3 gms. of meat extract, 10 gms. of peptone, and 8 gms. of sodium chloride adjusted to pH 7. Thirty c.c. are injected subcutaneously at one time. All wrinkles are smoothed out, and this is repeated every three days for four consecutive treatments. A rest period of two weeks is given and then the same course of treatment is repeated. He states that he has obtained clinical cures over a long period.

Rolfe (19) employs ionization with antiseptics. Theoretically, it should prove of value, but I have not observed permanent or long relief from this method, relief being obtained only while treatment is being given.

X-ray is a painless procedure, but I think it is much overrated, and itching is worse if it fails. Pruitt (20) claims fifteen to twenty cures.

Surgery, the undercutting operation, is resorted to when corrective measures by all these methods offer no relief. The patient requires hospitalization, and the pruritis may return in six months to one year. Flynn (21) claims ten cures after two to five years in twelve patients.

Gabriel (16) has had the Ciba Company make up a solution from a new formula which offers painlessness of injection and prolonged anesthesia. It is a solution of nupercaine (0.5%), phenol (1%), and benzyl-alcohol (10%) in almond oil.

It has not been placed on the market, but the Ciba Company has supplied me with ampules for experimental purposes on my private patients. I have used this solution with excellent results in 20 cases, freedom from pruritis lasting four to six months.

After cleansing the anal region 5 c.c. of this solution are injected under the itching area. I inject the posterior quadrant on the first visit and the lateral and anterior quadrants on subsequent visits. Pooling of the oily solution, infection, or eczema may lead to sloughing and a prolonged healing period.

For illustration two case records are presented.

Case I. O. D., age 23, a shipper, complained of considerable pruritis ani for two years. Procto-sigmoidoscopic and anoscopic examinations were negative for pathological changes. The perianal skin was thickened, and there were many skin folds. Numerous bleeding points from scratching were seen. Injection of 5 c.c. was made subcutaneously in posterior quadrant on June 8 with repeated injections on June 15, June 22, and June 27, taking in entire perianal region. Patient reported appreciable relief after the first injection and entire disappearance of symptoms after the fourth injection. Four months check-up finds the patient without symptoms.

Case II. W. G., female student, age 29, complained of perianal itching of nine months duration. Sigmoidoscopic and anoscopic examinations were negative. The skin was moist with bleeding points. Three injections were given with complete disappearance of symptoms for six months.

## SUMMARY

The possible causes of pruritis ani are many and their detection quite difficult. Every patient must be studied carefully and properly classified in order to relieve the underlying condition.

Many ways of combatting this condition have been enumerated.

A new solution with method of injection has been described. Twenty cases have been injected with this solution resulting in freedom from symptoms from four to six months to date.

## OBITUARY

## Dr. Lewis Stephan Pilcher

DR. Lewis Stephen Pilcher, scholar and editor for half a century of the oldest surgical journal in the United States, the *Annals of Surgery*, died this morning at eighty-nine years of age. Country school teacher, country practitioner, naval surgeon, student of tropical disease, anatomist, professor of surgery, editor, bibliophile, patriot—these nouns indicate a few of his many interests and activities over a long and intensely useful life.

Lewis Stephen Pilcher entered the University of Michigan at the age of thirteen, and took his bachelor's degree at seventeen, the youngest matriculant and the youngest graduate of that great institution. His master's degree was added within a year; and in that same year he entered upon medical study. This was in 1863 when the Civil War was raging. The next year found him with enough medical knowledge to volunteer as a hospital steward and throw himself into the thick of service to the sick and wounded. Then back to the University of Michigan and the doctor's degree in 1866. Many years later, 1900, this same institution conferred upon him the honorary degree of Doctor of Laws. Practice began in a rural district of Michigan at the age of twenty; at the same time, to guarantee a livelihood, teaching in the little schoolhouse by the blacksmith shop. He rode his horse across the countryside to the call of the sick, followed the current literature of medicine, and for diversion

read the classics in their original Greek and Latin.

The next move was to an internship in a Detroit Hospital. Then a post-graduate course in the hospitals of New York City. And then came the successful examination and appointment as Assistant Surgeon in the United States Navy, in 1867. His marriage, retirement from the Navy, and entrance into private practice, in 1872, all spelled romance and adventure. Then came the years of practice. But Pilcher wanted something more. He organized a dissecting room in his house. This expanded into an adjacent building. A museum and library grew up in connection with it. He dissected also at the Long Island College, and became Adjunct Professor of Anatomy, in 1879, and Surgeon to the Dispensary. In 1885 he was appointed Professor of Surgery at the New York Post Graduate Medical School.

In 1884 he became editor of the *Annals of Surgery*, which position he has occupied to the present day. This publication, beginning in 1884, was acquired in 1897, by J. B. Lippincott Company. The editorial policy and censorship of advertising have never been relinquished by the Editor. If we add to the fifty years of the *Annals of Surgery*, the seven years of the *Annals of Anatomy and Surgery*, and its predecessor which he inspired and dominated, this period of medical editorship establishes him as the dean of medical editors in the United States, if not in the world.

## SECTION VIII—*Editorial*

*The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Association is in no way responsible for editorial expressions.*

### GENERAL PRINCIPLES INVOLVED IN THE DIAGNOSIS OF GASTRO-INTESTINAL DISEASE

**A**CCURATE diagnosis in the field of gastro-intestinal disease is still a very difficult matter notwithstanding the tremendous amount of work of high character which has long been devoted to this field. Gastro-intestinal disease is one of the oldest recognized and best defined of the medical specialties. The subject of the physiology of the gastro-intestinal tract has been also one of the earliest and most intensively studied of the special systems. The field of gastro-intestinal disease always has been and still is one of the most attractive and important of the whole subject of internal medicine. The subject has never been relatively a neglected one nor has it ever failed to comprise among its workers many of the greatest of medical minds of the period for many generations past.

Dietary laws and rules have characterized almost every primitive as well as all civilized peoples, and yet we must honestly class as but little better than taboos and prejudices many of the dietary customs of the present day. Religion and racial custom still determine the so-called laws of dietetics far more certainly than do the results of scientific research and study.

The fact of the difficulty still existing in the diagnosis of gastro-intestinal disease is not the result of lack of facilities and opportunity offered by scientific progress and study. Mechanics and physics early contributed their methods to the study of the gastro-intestinal tract and a relatively correct interpretation of the primitive functions of the tube very promptly was recognized by all of the early anatomists. The Zapotecs and the Mayas among others, of our own hemisphere probably understood the anatomy of the tract very early, certainly long before the brake-like incubus of religion permitted adequate anatomical studies of the human body in Europe and perhaps even in Asia.

Long before chemistry had risen to the dignity of a science its methods of study were being applied also to the elucidation of gastro-intestinal problems, and this science in particular still remains one of the most fertile fields of study in connection with the subject. Experimental physiology almost may be said to have had its conception in studies of this field and it remains even to this day one of the most valuable methods of study, present and future.

The discovery of the microscope almost immediately contributed its help in direct application to the study of the physiology and pathology of the digestive tract, and at least in diagnosis we but stand on the threshold of its possible contributions to the subject.

Opening address.  
\*Read before the Fo'tnight. Session of 1934, New York Academy of Medicine, Oct. 21, 1934.  
†Attending Physician to Bellevue Hospital, Fourth Serv...  
Submitted October 24, 1934.

Radiology, as you shall hear later, has become one of our most effective arms in the conquest of gastro-intestinal disease, and yet our errors in the diagnosis of disturbances of the gastro-intestinal tract are of shocking frequency, and our knowledge of selective dietetics still rates below that of the instinct of the lower animals. As a matter of fact our dietetic habits are still more dictated by instinct, custom and ancestry, sometimes even by religion, than by scientific fact.

I am fully aware that my statements must seem to many of you who have considered the matter, as very broad and rash. Especially must they seem so to those of our cloth who have devoted their chief interests to this field throughout long and rich professional lives.

I believe however that a dispassionate weighing of the facts of diagnostic error in this field as shown in the dead house of any large general hospital will serve to substantiate my statements in general. The timeliness of such a period of intensive study as we are inaugurating tonight will no doubt be apparent to us all before the days of the period of this serious consideration are over.

There are of course reasons for our particular frailties and inadequacies in this field of diagnosis. I think it will be helpful, if not flattering, for us to consider a few of them. Many, if not most, of our failures are due to the extreme complexity of the subject and to the delicate integration which the gastro-intestinal tract bears to all the other functions of the human body both in health and in disease.

We may almost correctly state that there are no general or special disturbances of the body which do not manifest themselves in some degree at least by symptoms or signs of gastro-intestinal disorder. Consider for example the very familiar symptom of nausea. It appears as an evidence of fright, of worry, and of many if not most other forms of mental and nervous disease. It is developed by vertigo; it is a sign of pregnancy; it is one of the initial symptoms of most of the infections; it is intimately associated with visual disturbances, with trauma, shock, malnutrition, and with most of the surgical as well as medical diseases of the abdomen. It is frequent in pneumonia and in trauma of the thorax, even with those of the extremities. I believe that one may almost say that it is the most frequent symptom of all diseases of the body and of many physiological variations. It is even occasioned by political conditions, particularly at the present time. This is but an example.

The welfare of the entire body is essentially dependent on the integrity of the gastro-intestinal tract. Most disease conditions of any of the systems, cause not only symptoms but abnormal signs also of the gastro-intestinal tract. Worry and fright check or limit gastro-intestinal secretion, favor abnormal putrefaction and fermentation, delay or paralyze the all-

essential peristalsis, manifested by chemical and radiographic signs familiar to us all. Innumerable other states and diseases far remote anatomically from the gastro-intestinal tube also wreck changes of the same character.

Gastro-intestinal symptoms, signs and pathology are among the most constant evidences of cardio-vascular disease and even the properly trained cardiologist must know how to distinguish these symptoms; he also must be a gastro-enterologist. The student of renal disease constantly is called upon to differentiate gastro-intestinal signs and symptoms due to kidney defects from those produced by integral pathology of the gastro-intestinal tract or perhaps from identical findings and symptoms primarily caused by widely distant and entirely foreign pathology to that of the organs in which he is primarily most concerned.

Genital and endocrine diseases cause marked vagaries of the functions and signs of the digestive tube. Even the endocrinologist and the obstetrician must be serious students of gastro-enterology. This is equally true of every speciality of medicine. The student of dietetics in particular must familiarize himself with the ethnology, the history and the sociology of gastro-enterology. Woe betide the patient of the specialist in pulmonary disease whose attendant never explores below the costal margins.

I think that I have presented sufficient excuse for the tremendous difficulties of accurate diagnosis in gastro-intestinal disease, and incidentally I trust I have pointed out the great need which every practitioner and every research worker has for a broad general knowledge at least of the general principles concerned in the diagnosis of gastro-intestinal disturbances.

It is of course axiomatic, for the same reasons that the specialist in the diagnosis as well as the therapeutics of the gastro-intestinal tract must be most broadly informed on general diseases and especially concerning those conditions such for example as pernicious anemia, sprue and the like which are strikingly evidenced by gastro-intestinal signs and symptoms.

The gastroenterologist who is not an earnest student of internal medicine in particular is a very poor gastroenterologist. I say this in no disparagement of the gastroenterological specialist or for that matter of any other specialist, for true specialization in this day and stage of medical evolution is indispensable, and especially so in the tremendous field of gastroenterological diagnosis which demands not only broad learning but also very high technical training and ability in the very difficult and highly intricate methods of this speciality. Concerning this you will hear very much from far greater authority within the next few days. My purpose is to point out as convincingly as possible the absolute need for breadth of vision on the part of every one of us and at the same for as high a degree of technical perfection in the methods of diagnosis as is possible for any of us to attain. Even with such equipment, error in this difficult field is certain to occur all too frequently with the very best of us, and it is our hope that the frank discussion, earnest study and broad demonstrations which we are to receive within the next few days will return all of us to our offices and clinics better prepared to recognize and to treat the patient suffering from gastro-intestinal symptoms and pathology.

It is not my function this evening to enter into the technical details of the diagnosis of gastro-intestinal diseases but rather to point out the general principles which apply to them. In extension of the ideas presented above, I would then first state that in every case of suspected gastro-intestinal disease a preliminary general examination should be made so that gastro-intestinal disorders of extra visceral origin may be first detected. This should eliminate from confusion such conditions as reflex vomiting, pernicious anemia, sprue, cerebral disease and many other conditions in which treatment should be directed primarily to pathology outside the gastro-intestinal tract.

I feel also that second consideration should be accorded to the possibility of gastro-intestinal signs and symptoms developing as a result of disease factors introduced entirely from without. Such infections as uncinariasis for example, and other similar conditions may be readily enough confused with instances of gastric carcinoma or ulcer as they are in no small number of cases. Inadequate, superabundant, unbalanced or unaccustomed diet must be also considered as responsible for many signs and symptoms of gastro-intestinal disease and one must recall these possibilities before assuming primary pathology of the tract itself.

In relation to these dietetic problems as a cause of gastro-intestinal disease it must be recognized that racial and ancestral customs play a very important part particularly when radical changes in physical habits, in climate, altitude and in sun and light conditions exist. Roughly stated, it will be found as a general rule that the most desirable diet and dietary customs in any locality will be those which the natives in that area habitually select.

As has already been stated, it is not the function of this paper to consider in and detail the special technic of diagnostic examinations since all these are to be taken up in detail both in lecture and in demonstration. There are however certain general points in the diagnosis which properly fall to my function for presentation.

The first of these is to point out that in diagnosis as in treatment, the gastro-intestinal tract can not be considered as separated from the general organism. On the contrary it is only when the general condition of the body as a whole is fully appraised that we are able properly to evaluate the data which lead up to adequate diagnosis; hence I feel that final diagnosis can only be arrived at properly after a general examination of the entire body has been conducted and weighed in relation to the evidence of history and environmental conditions. This must be then supplemented by a careful special examination of the gastro-intestinal tract by whatever special technic may be indicated by the evidence elicited.

In the course of this seminar you will be appraised fully of all of the newer methods of examination and of the invaluable data which they are able to present to the diagnostician. You will in particular be authoritatively informed of the tremendous contributions of radiography to this special field of medicine.

In regard to the radiographic findings in particular I wish however to sound a warning note. So accurate, so valuable has the roentgenographic measures for the diagnosis of gastro-intestinal pathology become that many clinicians, especially some of the younger school

have, I feel, come to rely too exclusively either in a positive or in a negative way on X-ray findings in diagnosis. Too often in the work-up of average hospital cases of gastro-intestinal disease I find that the X-ray findings only are sought, with an almost complete ignoring of the tremendously valuable lessons which chemical examinations of the secretions are still capable of furnishing us. Too often the intern resorts to the use of the fluoroscope and X-ray plate before, rather than after, a proper history has been taken. Chemical and microscopic examinations are neglected or undervalued in the face of positive or negative radiographic facts, and by no means infrequently, grave errors in diagnosis and in treatment therefore ensue. New methods have much supplemented, but rarely displaced the old.

Quite as often also do we find that the physical examination has been slighted or even omitted. Too frequently because of negative X-ray findings, the rectoscope and sigmoidoscope and their great possibilities in the way of accurate diagnosis are forgotten. Too often, far too frequently, even is the simple procedure of a digital examination and inspection of the anus and rectum omitted under the excuse that the X-ray findings are reported as negative.

These errors of neglect are not the fault of the radiographer; they are even very commonly the result of his too great efficiency in the diagnosis of gastro-intestinal pathology so that the other methods of examination are neglected. I also feel that recognizing as we must the high technical skill of the average modern radiographer, that the clinical diagnostician neglects to view himself the films assembled by the expert, as it were, through the eyes of the clinician, and too often also does the clinician forget the tremendous value which may be afforded him by his own use of the fluoroscope, again viewed thru the eyes of the clinician, familiar as he should be with the chemical, microscopic and physical aspects of the case, all thrown as it were, on the screen of that most valuable of all diagnostic methods, a well and personally taken history.

Finally I would again impress upon all of you the very great variations which occur in the gastro-intestinal tract still within the wide range of physiological idiosyncrasy—very frequently these almost imperceptibly verge over the line into real morphological or chemical pathology, while yet still capable of correction along physiological methods of treatment.

The gastro-enterologist must be a very broad man, one familiar with many fields within the realm of medicine and yet superficially viewed as far from the definite subject of gastro-intestinal disease. Not for one moment may he be allowed to forget that gastro-intestinal physiology and pathology are inextricably blended with the functions of the body as a whole and as a result of its reactions to environment.

Harlow Brooks, New York City, New York.

#### ENTEROGASTRONE

**T**HE original observation of Ewald and Boas (1886) that the presence of undigested fat in the upper intestine causes an inhibition of gastric motor activity has been repeatedly confirmed. That fat has a similar inhibitory effect on gastric secretion was demonstrated by Pavlov and his students (Labassov). The nature of the inhibitory mechanism concerned has

been considered to be entirely nervous until recently.

In 1926 Farrell and Ivy (1) introduced a new concept concerning the mechanism of the inhibition when they observed inhibition of an auto-transplanted gastric pouch following the introduction of fat into the main stomach. This demonstrated that a humoral agency must be considered as playing a rôle in the gastric inhibition caused by fat. This was soon confirmed by Lim and his colleagues (2). Later, Feng, Hon and Lim (3) found that fat also inhibited the secretion of a transplanted gastric pouch, and that the inhibitory humoral agent was not some post-absorptive circulating substance originating from digested fat. Quigley, Zetteman and Ivy (4) similarly found the inhibition of motility caused by fat was not due to post-absorptive circulating fatty substances.

Quigley and Rneips (5) have recently submitted evidence showing that glucose acting in the upper intestine inhibits gastric motility by some humoral agency and that the agent was not the absorbed circulating glucose.

These observations, of course, suggested the possibility that when undigested fat (fatty digests stimulate secretion and motility) contacts the upper intestinal mucosa a chalone (inhibitory autacoid) is elaborated and carried by the blood (fatty lymph is inactive) to the stomach where it causes inhibition of motility and secretion. If this hypothesis were true such an inhibitory substance should be extractable from the upper intestinal mucosa.

In fact, Kosaka and Lim (6) have found that when relatively large doses of a cholecystokinin preparation, supplied by the author, were injected intravenously gastric secretion was inhibited. This stimulated Lim and his colleagues (7) to determine whether a specific substance might be isolated from intestinal mucosa, which would inhibit gastric activity without having an effect on pancreatic and biliary flow. They were successful in preparing such an extract, although they found that similarly prepared extracts of muscle and gastric mucosa also caused inhibition, but to a less extent than extracts of intestinal mucosa. Because of the strong presumptive evidence, they considered the humoral inhibitory, or chalone, substance and the inhibitory substance in their extract to be identical. So, they named this gastric inhibitory principle of intestinal extracts "enterogastrone."

More recently, Lim, Ling and Liu (8) have reported that they have been able to remove all the vaso-depressor and toxic substances from the active extract. Independently, Greengard, Maison and Ivy (9) have also been able to prepare an extract which is free from objectively detectable toxic substances, and which inhibits both secretion and motility in the dog. However, it is believed that the preparation is not yet sufficiently pure to warrant injections into man.

It would appear that enterogastrone is a substance which may prove to be of practical value. Any substance which possesses the gastric inhibitory attributes of atropine without its undesirable side effects would be of practical value in certain cases of "peptic" ulcer. It is not known whether enterogastrone is active hypodermatically, which will depend largely on

its molecular size. If it is found that it must be administered intravenously, like secretin and cholecystokin, in order to obtain effective responses, its

practical therapeutic usefulness will, of course, be much more limited.

A. C. Ivy, Chicago, Ill.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

*This Journal is not responsible for the opinions, decisions or groupings expressed by reviewers of books or pamphlets. For the guidance of readers, an attempt is made to indicate the relative worth of reviewed material by placing "stars"—★ in connection with the reviews. The greater the number of "stars," the more agreeably and importantly has the book or pamphlet impressed the reviewer.*

★★★★ *Treatment by Diet*, by Clifford J. Barborka, M.D., Sc.D., F.A.C.P., Department of Medicine, Northwestern University School of Medicine, Chicago; formerly consulting Physician, Mayo Clinic, Rochester, Minnesota; 615 pages, Illustrated. Published, October, 1934, by J. B. Lippincott Company, Philadelphia, Pa. Price \$5.00.

Occasionally, without a lot of "just-wait-and-see-what's coming" type of publicity, a member of our profession quietly assembles his own and others' data in a particular field of medicine, discriminatingly evaluates the material in the light of an extensive clinical experience and private patient management, retains what is dependable, chucks out what is unproved or ephemeral, and then compiles a sincere, thoroughly useful, practical book.

Dr. Barborka has accomplished just that objective in his "Treatment by Diet": every page "makes sense" and this sense is carried to us in a scholarly, usable fashion.

McLester was the first of this country's internists to bring forward a book which considered diet not alone from its scientific and nutritional aspects but, what was more significant, diet such as Americans actually eat. He, it was, who brought us foods which are not foreign to our appetites and tastes and liberally supplemented with all sorts of patented, high-priced, unproved, faddistic, *ausländischer* conglomerations whose attempted ingestion often proves enough to gag a buzzard.

Barborka has accepted McLester's rationality, and progressed from it not only to emphasize diet, *per se*, but to demonstrate dietetics as a medium of therapy on a par with treatment by drugs or other accepted modes of clinical and private patient management. He has performed this exceedingly difficult task in a useful, impersonal, unbiased, unprejudiced manner. Such method of considering food as a therapeutic agent, the reviewer feels is a distinct—and safely he may add, a definitely American—advance.

Perusal of many foreign (and some homeland) publications demonstrates that dietotherapy has seemed to be a field of activity in which the longer certain clinicians have dwelt, the greater have been their tendencies to develop fixed ideas, narrowed visions, faddism or the temptation to accept half truths and then to wander aimlessly over the horizon of fact into the nebulous realm of supposition, theory, fetishism. So general has been this tendency in books and in journals, that "dietetics"—whether in health or in disease—until the advent of McLester's, and now Barborka's, unique publications, has meant little more than "just another diet-book," bywords among doctors. Their bookshelves carry a dozen or more volumes on the topic, many of the works "practically new," rarely used, pages uncreased, often even uncut. All of which eloquently indicates that, with rare exceptions, diet as a form of therapy either has been presented miserably to the practitioner who, as his shelves show, is eager to learn how to employ it in every-day practice or that dietotherapy admits of maintaining so few positive positions that responsible writers have shunned the subject. Those who have risked stretching their theses to book length, largely have been copyists, meagre in experience, purveyors of spurious or half baked facts, or have *written merely for posterity*: for certainly, little of what they have set down is read by, or has been found acceptable to, the present generation of physicians still able to cerebrate or possessed with a sense of values—or of humor!

Dr. Barborka's method of approach is distinctive and logical. First, a concise discussion of diet as it is essential to the maintenance of health is given. Here the economy of words is commendable, but even so the subject in all its phases adequately is covered. "Parts I and II" limited to 42 pages embrace as much fundamental material as usually one finds elaborated to make a fat tome. Somewhere in the Author's ancestry must lurk a bit of Scotch, for few words are wasted. Rarely has the reviewer observed such a lot of matter comprised into so few pages. The discussion admirably qualifies the reader to progress to "Part

III"—the chief reason for publishing the book—namely, "Diet in Disease."

In this section of approximately 500 pages, we are given a most helpful—and to us—an original manner of presentation of the treatment of disease by diet. Each disease or syndrome is headed by a "box" which contains a pertinent summary of the pathologic aspects (when possible) or the *nature of the disease* and the *object of diet* in its treatment. These summaries are appreciated at a glance while, below, the text gives briefly the essential clinical features of the ailment and sets forth the important factors bearing upon the significance of diet as an agent concerned with treatment. Prior to presenting specific diets, the effects or the correlation of medicinal or other modes of management which many be exhibited, judiciously are discussed. The variation in clinical signs and symptoms and the bearing of such upon dietetic changes are emphasized. Incidentally it may be observed that in these considerations, the Author exhibits a sound knowledge of the basic clinical manifestation of disease.

The diets, themselves, are extremely well presented, not alone from the standpoints of their caloric values, the relative quantities of protein, carbohydrate and fat, but they comprise refreshing varieties of food stuffs; the addition of tabulations indicating simple, easily followed, household measures, makes particularly helpful the quantitative allowances of food stuffs to physicians, nurses or other attendants who are not trained to the accuracy called for by scale-weighing or have not suitable scales available. Photographs illustrative of kinds, varieties and quantities of foods furnish visible and not easily forgotten impressions of what constitute suitable, correct and therapeutically adequate meals.

Especially complete and sound are the discussions of the treatment by diet of disorders of metabolism—diabetes mellitus, gout, obesity, and emaciation. In this grouping, the Author chooses also to include nephritis, an ailment which other clinicians may include in other classifications, but, in view of recent knowledge supplemented by Dr. Barborka's discussion, justification for so doing reasonably is admissible. At any rate, his presentation is excellent and more than usually definite.

The Sections devoted to the anemias, peptic ulcer, constipation and "deficiency diseases" (an ever expanding list—a list whose individual components in not all instances is yet so sharply defined as one would like and in which future years may qualify its length by enlargement or limitation) represent not only the down-to-date conceptions of conservative experienced clinicians, but include not a little original thought on the part of the Author. Personally, the reviewer would wish for a rather more liberal discussion of the dietotherapy in peptic ulcer than one obtains, but on the whole, Dr. Barborka satisfactorily presents popular conceptions and simply followed instructions with regard to feeding.

Probably the Author nodded a bit (who would not when "boiling down" for practical use the immense literature and material on this and other topics comprising this book?) when he states as one of the dietetic precepts in ulcer management, "avoid foods that stimulate gastric secretion" and then follows by including "protein foods" as "desirable" inasmuch as "they (milk and eggs) bind the free hydrochloric acid

present in the stomach and aid in neutralizing the acidity." Recent researches, particularly those of Babkin and his Associates at McGill University as well as those of observant clinicians for more than fifteen years past (Jarotsky and others) have demonstrated that the proteins of milk and of egg stimulate both acid and pepsin secretion in excess of their capacity to combine with the digestants so stimulated. The fluid protein of milk is less stimulative than is the semi-fluid protein of egg: in fact, if one employs egg in ulcer diet, the investigations of Rehfuess and Hawk would indicate that chopped, hard-boiled egg most satisfactorily "binds" free acid and most readily "neutralizes" peptic activity. Very likely, the "milk and soft egg diet" used in the dietotherapy of gastric ulcer owes whatever efficacy it may have by being fluid and thus, rapidly passing from the stomach and the duodenum so that in the lower duodenum and upper jejunum digestion may take place, thereby leaving the stomach (and the duodenum—the most common site of ulcer) relatively at rest. Digestion of a milk and egg mixture in such position in the alimentary tract may permit production of the hormone-like, gastric secretion, inhibitory agent "Enterogastron" isolated by Ivy. Hence the "milk and egg diet" for gastric ulcer treatment proves to be put indirectly advantageous. All in all, the consensus of clinical opinion regarding the initial diet for gastric ulcer management, when there exists no pyloric obstruction, continued spasm or organic blockage, rationally would seem to consist of fluid or semi-fluid carbohydrates and fats (Babkin, *et al* and, most recently Armine Alley).

However, Dr. Barborka—as stated—has clung to popular concepts in ulcer dietotherapy and, as happens so commonly, with the majority of clinicians, has designated no particular variation in diet for duodenal ulcer—the most common "peptic" lesion. It is significant of the times, that the Author has stressed the need for vitamins in ulcer diet and has cautioned against the needless, and often reckless, exhibition of alkalies. Therapy by "gastric mucin" (really a food and not so "protectant" a medicinal agent as was first extolled by its proponents) properly receives non-committal comment. Its more easily ingested vegetable prototype "Oktrin" is not mentioned. Dr. Barborka's "Ulcer Diet" lists are quite adequate; especially helpful should prove those submitted for dietetic management following operative interference.

Very rational for the aid possible *via* diet are the suggestions given for care in circulatory and febrile ailments, tuberculosis, disturbances (non-ulcerative or malignant) of the oesophagus, stomach, biliary tract and liver and the intestines.

Especially valuable is the consideration of the Ketogenic Diet and the disturbances in which it is applicable. Here the Author speaks with especial authority, for probably no other clinician has been so great a factor in its origination, modification and exhibition as he. Perhaps, for the first time, he has presented our profession with reliable examples of this type of diet in the therapy of epilepsy, migraine, asthma and chronic urinary infections. And with it all—despite his close connection with the elaboration of the Ketogenic Diet—Dr. Barborka has been rational and conservative to a degree refreshingly acceptable. In fact, this Section demonstrates, more than any other in the

book, how firmly balanced is the Author's conceptions of dietotherapy. More than ordinary equilibrium is demanded when one considers a subject very close to his heart or in a field where one has so notably pioneered as has Dr. Barborka in the practical application of the Ketogenic Diet for relief of a troublesome group of pathologic syndromata.

But ten pages are devoted to "Food Allergy"—a significant fact in view of the Author's broad grasp of principles of dietotherapy. Such limited allotment of space should serve notice as to the extent of our actual knowledge of what really is known and is clinically available in the dietetic therapy of that bewildering group of disturbances which certain individuals have designated, "allergic." The essentials, however, are contained in Dr. Barborka's ten pages. Whole volumes and an enormous journal literature have been written on unproved and multitudinous and confusing aspects of what within a decade has created the so-called specialty of "Allergist."

Skin lesions, arthritis, pregnancy and lactation, dental caries and routine hospital diets (a subject well handled, but which always causes "goose-fleshing" to the reviewer inasmuch as he personally shudders at the idea of adapting an ill patient to any routine "diet") doubtless, a necessity in a book which aims to cover the subject and satisfy everyone, and special methods of feeding conclude this encyclopedic modern discussion of treatment by diet.

There is a very complete index; the bibliography is extensive and well selected; the index proved accurate to twenty tests.

The book is a characteristic Lippincott product: convenient in size, of appropriate weight, well bound, made of satisfyingly white paper which well takes type impressions, typographically attractive, well "proof-read" and reasonable in price (a very welcome feature in these days so financially discouraging to physicians).

The reviewer cannot recall when so much usable, accurate, dependable, down-to-date knowledge—particularly on dietotherapy—has been offered to doctors, nurses, hospitals, investigators, medical students, internes, so well arranged, so authoritative and for so little cash.

Furthermore, he is unable to see how anyone who desires seriously to employ diet in the everyday treatment of disease, can feel comfortable in his practice without Dr. Barborka's really admirable book. Both to Author and Publisher is our profession indebted, for they have given us a really standard, authoritative work—one which we venture to prophesy will command wide acceptance and will enjoy many future revisions to meet changing conditions in a very labile but necessary field of practice.

Frank Smithies.

★ ★ ★ *Cirugia Gastrica*. Volume 1, by Dr. M. Corachan, Barcelona, Salvat Editions, 1934.

Here is one of the most remarkable books we have seen in a long time. It is not only well written and beautifully illustrated with many photographs in color, but it is bound and gotten up like a presentation copy.

The author is professor of surgical pathology at the University, and chief surgeon to a large hospital

in Barcelona. It is remarkable for a European book that the large bibliography contains abundant references to the work of men, not only in Spain, but also in France, England, Germany and the United States.

It is unfortunate that few American physicians can read Spanish, because otherwise this book would make a nice addition to their libraries. As far as we know there is no book in English which covers the field so extensively or so beautifully as this volume and its companion, which will appear later, will do.

Much space is given, as one would expect, to the problems of ulcer and cancer of the stomach. Much space is given also to a discussion of the rarer lesions of the stomach.

The only criticism that we feel inclined to make is that we wish the writer had trusted more to his own experience and wisdom and less to his extensive knowledge of what others have written.

The second volume is to contain a chapter on pre and post-operative care, on anesthesia, indications for, and technique of, the various operations on the stomach rare or disused operations on the stomach that have been operated on and the results of various operations, and on the bad results sometimes obtained after gastro-enterostomy and gastrectomy.

Walter C. Alvarez, Rochester, Minn.

★ ★ ★ *Food for the Diabetic*, by Mary P. Huddleson, Consulting Dietitian. The MacMillan Company.

This book was written for the diabetic patient. In 103 pages it well fulfills its purpose in giving the patient all the information needed to carry out the instructions and the program outlined by his physician. Throughout the book the patient is impressed with the importance of frequent visits to his physician. Probably one of the most important points of emphasis is the diabetic program which is so definitely outlined in the first part. In this program, detailed instruction is given the diabetic patient for his daily care, how to prevent emergencies, and how to meet emergencies should they occur.

The book is divided into three sections: Section 1—Diabetes; Section 2—The Diabetic Diet; Section 3—Details for the Diabetic Diet.

In Section 1, emphasis is placed upon the diabetic diet meeting the requirements of the normal diet. The Author gives full explanation as to what a normal diet must contain. A simple definition of diabetes is given and the subject is discussed very clearly from the standpoint of the layman.

In Section 2, detailed instruction is given in measuring foods, how to calculate the food prescription, food-tables, meals for the diabetic and recipes for the diabetic are also clearly outlined. A method is given for working out the diet according to the physician's food prescription for the total carbohydrate, protein and fat. In the tables of food equivalents the amounts are expressed in gram weight and in common household measurements—standard half pint measuring cup, tablespoon and teaspoon. The size of a slice of bread or meat and the diameter of certain fruits are given in inches. Very practical recipes are given which the patient is taught to calculate in his daily diet prescription.

\*Editor Journal American Dietetic Association.

In Section 3, a good description is presented on how to test urine and how to give insulin. In the last chapter good suggestions are given on the prevention of diabetes, especially in those families or races where there is a tendency to diabetes.

This book offers a very clear understanding of the diabetic diet, and many variations which may be made from a diet prescription. The plan of the instruction outlined is very clear to the patient who has been taught by this method. The writer has stated that there are several methods for the calculation of dia-

betic diets "each easy for the originator but difficult for others." Therefore should a patient, who has been taught by some other method than the Author outlines be given this book for further instruction in planning his diet, he would probably be much confused.

Other subjects treated in the book should be most valuable to any patient with diabetes regardless of the method he has been taught to calculate his diet and plan their daily menus.

Clifford J. Barborka, Chicago, Ill.

## SECTION XII—"The Clinic"

### Dyspepsia and Gastric Bleeding Due to Chronic Appendicitis

By

MARKS S. SHAINÉ, M.D.

210 W. 70TH ST., NEW YORK CITY, NEW YORK

FOLLOWING the huge number of appendectomies which were performed indiscriminately on the most meagre evidence in the early years of this century, there set in a violent reaction in which the whole concept of chronic appendicitis as a clinical entity and as a cause of dyspepsia was entirely rejected. The profession is but now awakening to the fact that the pendulum had on both occasions swung too far, first one way then the other; the truth regarding chronic appendicitis is emerging more and more clearly. Many skeptics still deride the diagnosis of chronic appendicitis whether made on the basis of clinical signs and symptoms or of a roentgenological study.

The unbiased observer who has followed the literature on the subject and who has had the opportunity to observe the abrupt and permanent disappearance of a chronic "dyspepsia" following appendectomy will no longer deny the casual relationship between the two conditions. But it is far less widely known that a chronically diseased appendix may be the cause of gastric or intestinal bleeding in the absence of other gastro-intestinal disease. Attention to this fact has been drawn by several writers (1, 2).

The following case history offers evidence, proved at operation, that a chronically diseased appendix may

cause not only intermittent attacks of dyspepsia but also gastric bleeding.

#### CASE REPORT

S. G., aged 58, referred by Dr. Jacob Sobel, gave a history of anorexia dating back to 1922. He first presented himself for examination on July 6th, 1926, complaining that for four weeks he had had pain and burning in the epigastrium and left hypochondrium, which began two hours after meals and were relieved by soda. He also complained of belching, sour regurgitations, constipation and loss of weight.

Physical examination showed a pale, thin man, five feet eight inches in height, whose weight was 109 lbs., neurologically negative, a blood pressure of 130/80, heart and lungs nega-

tive, abdomen negative, *no tenderness in McBurney's region*. Except for some internal hemorrhoids, the sigmoidoscope was negative.

A gastro-intestinal X-ray examination was negative except for ptosis and a small gastric residue at six hours. He was put on a high caloric diet with sufficient roughage, oil enemata, mineral oil and tonics. His symptoms improved and he was discharged in December, 1928. His weight was 120½ lbs.

He was next seen in April, 1929, with symptoms very similar to those complained of in 1926. X-ray examination showed a definite and constant deformity of the duodenal cap, and a six hour gastric residue. He was put on ambulatory ulcer treatment and was discharged, improved, after four weeks.

In November, 1930, his symptoms returned and the X-ray examination again revealed a constant duodenal cap deformity.

After a month's treatment similar to that in the preceding attack, his symptoms were relieved and he did not return until November 9th, 1933. He now complained of heartburn, sour regurgitation and vomiting of coffee colored material which gave a positive benzydine test. The Ewald test showed a hyperacidity and a positive benzydine test. Lavage showed a large gastric food residue six and seven hours after a meal. His weight was now 109 lbs. The X-ray examination showed a narrowing and a deformity in the pyloric region. The duodenal cap was poorly filled and there was puddling in the second portion of the duodenum. It was decided that the patient had either a large ulcer or a new growth.

With the hope that it was an ulcer, he was put to bed for three weeks on a Sippy regime and his symptoms subsided. But ten days after he left the hospital, the distress, the heartburn and the coffee colored vomiting returned. He was re-admitted to the hospital.

A laparotomy was performed by Dr. Louis Friedman. The stomach and duodenum were found absolutely normal. There were no thickening, no induration, no deformity and no sign of adhesions. The gall bladder, liver, pancreas and colon were normal, with no adhesions. The distal half of the appendix was distended to about three times its normal width and it contained a large fecolith. Appendectomy was performed. The patient made an uneventful recovery. He has remained well since the operation, has no symptoms and has gained over ten pounds in weight.

#### SUMMARY

The history is presented of a patient who for years had digestive

symptoms with hematemesis. The X-ray showed a deformity in the stomach and duodenum. Laparotomy showed no pathological lesion except a diseased appendix with a large fecolith.

## CHRONIC AMEBIASIS, EXHIBITING DYSENTERY FOR THIRTY YEARS

By

M. A. DESMOND, M.D.  
SANTA MONICA, CALIF.

CASE report: Patient, L. H., male, Spanish War Veteran, age 66, white.

Submitted Nov. 8, 1934.

# The new LAROSTIDIN TREATMENT

for peptic ulcer . .

The Larostidin Treatment consists of consecutive daily intramuscular injections of 5 cc. (1 ampul) each, for an average length of time of about 24 days. Inject alternately in arms or gluteal muscles, preferably the latter. The injection should be made slowly, with gradual withdrawal of the needle . . . . .

*Hospitalization is not necessary  
No interference with normal everyday routine*

*Indeed, many cases hospitalized prior to the beginning of treatment become ambulant before the injections are all given—and there is no rigid dietary schedule or interference with the patient's normal everyday routine.*

#### TYPICAL MANIFESTATIONS

- (a) After about 4 or 5 injections—pain usually disappears.
- (b) After about 10 days—average diet is tolerated.
- (c) At end of treatment—there is usually remission of all symptoms: food intolerance, gastric pain, hyperacidity; improvement indicated by normal peristalsis and emptying time; absence of spasticity.

Make  
this test

Take five of your peptic ulcer patients of longest standing, patients who have resisted other treatments or have had recurrences. Explain the Larostidin treatment, and the success being reported with it. Note the daily reports of those who take it; and at the end figure your percentage of successful treatments for the group. We are confident you will use Larostidin thereafter.

AMPULS, 5 cc., cartons of 6.

**HOFFMANN-LA ROCHE . . Nutley, New Jersey**

March 20th, 1934, this patient was bedridden, extremely attenuated; very weak; abdomen distended; no indication of color to the skin; bowel movements from 10 to 25 per day; weight 100 pounds; mentally depressed; hemoglobin 27%; color index 0.9; leucocytes 5,600; erythrocytes 1,140,000. The blood smears showed of 100 cells counted, lymphocytes 28, large mon. 6, poly. 65, basophiles 1. The Wassermann was negative. The stool revealed cysts of *ameba hist.* My diagnosis was chronic amebiasis, chronic colitis, severe secondary anemia. At this point I may say that Mr. H. was former hospital steward in the Philippines and Mrs. H. a nurse. The dysentery began in 1904 at Manilla, P. I. (See last paragraph).

The following medication was ordered; 20 min. liquid Alpha Naphco hourly in water and orange juice supplemented by 12 Enteric Coated Capsules of the Jelly of Alpha Naphco, daily.

The third night after beginning medication, the dysentery was checked to the extent that Mr. H. had no b.m. during the night, and thereafter the number of b.m.'s. was greatly reduced. He continued on the above mentioned treatment until the 11th of April, at which time his condition was much improved, hemoglobin 40%, b.m. 1 to 2 daily, patient sleeping well, appetite returning, color returning, psychically much encouraged, in fact patient was now up and about the house. Lextron was now ordered. May 15th hemoglobin 60%, weight now 155 pounds and color good. May 28th hemoglobin 68%, weight 156½ pounds. After the 5th of June, the patient discontinued the ingestion of the germicidal medications i.e. Alpha Naphco liquid and the capsules, but continued on Lextron.

His present weight is 174½ pounds, eats and sleeps well, b.m.'s 2 to 3 daily. The laboratory report on two recent stool examinations ran as follows: feces semi-solid formed, light brown color, normal appearance; benzedine reaction for blood, negative. Microscopic examination revealed neither active nor encysted forms of any type of protozoa.

In connection with the above case, I wish to quote the data of an examination of date, May 25th, 1931, as given me by the Case Correspondent, War Service of the American Red Cross as follows:

## CELLU CANNED FRUIT JUICE-PAK

A new product consisting of choice tree ripened fruit packed, without the addition of sugar, in fresh undiluted juice expressed from fruits of the same kind.

### DIETARY USES

Diets in which a sugared product is not desired, quantitative diets in which a fruit of known food value is recommended, diets which stress mineral value are particularly mentioned as mediums to which Juice-Pak Fruits are particularly adapted. The use of Juice-Pak Fruits in quantitative diets for Diabetics helps to maintain a less variable source of Carbohydrate value than is possible in using fresh fruits. The total available Carbohydrate values are listed here for your information. The Carbohydrate, Protein, Fat and Mineral values are stated on the labels of all Juice-Pak Fruits to facilitate their accurate computation in the diet.

### Carbohydrate Values

|                     |     |
|---------------------|-----|
| Apricots            | 11% |
| Blueberries         | 10% |
| Royal Anne Cherries | 14% |
| Yellow Cl'g Peaches | 9%  |
| Bartlett Pears      | 11% |
| Sliced Pineapple    | 15% |
| Crushed Pineapple   | 13% |
| Pineapple Juice     | 13% |
| Red Raspberries     | 9%  |
| Strawberries        | 7%  |

We would like to send you more information on these Fruits.

Pin to your letterhead and mail.

Send us a catalogue describing Juice-Pak Fruits.

D. D. N., 3-35.

## Vaccine Therapy in Ulcerative Colitis\*

*Thesis By*

SIBRAND LUPS (Arts)†

GRONINGEN, HOLLAND

*Translated and Edited by*

ABEL J. BAKER, M.D., F.A.C.P.

GRAND RAPIDS, MICHIGAN

### HISTORICAL REVIEW

CLINICAL cases of ulcerative colitis which differed considerably from the types of dysentery usually encountered, in the fact that they did not respond to medical treatment, were first reported in the latter part of the previous century. Until about 1902, it was mainly surgeons who observed and described the characteristics of this condition. The great similarity of this disease with dysentery, however, often led to much confusion. It is, therefore, not to be wondered at that many clinicians considered the affection as a peculiar form of dysentery. Even until recently, opinions on the question as to whether or not ulcerative colitis is an independent disease have been much debated. Its chronologic development, therefore, can hardly be discussed, hence, a review of the various opinions by different clinicians is not based on any chronological order. Those investigators who have expressed opinions as to whether or not ulcerative colitis strictly is a disease entity can be divided into three groups as follows: (1) Those who considered it as belonging to the group of dysenteries. (2) Those who, in some respects, considered it an independent disease but nevertheless admitted many arguments against this view and therefore still considered it as one belonging to the group of dysenteries. (3) Those who considered it strictly as an independent disease.

In the latter part of the nineteenth century most clinicians considered this affection which later was called "ulcerative colitis" as belonging to the dysentery group, even after 1903, when Boas expressed the view that ulcerative colitis was an independent disease. About 1914, however, there was a marked change in the viewpoints of many observers on this question although many still felt that it was of dysenteric origin. They knew full well that only in a few cases true dysenteric organisms were found. Moreover, the therapeutic effect of anti-dysenteric serum inclined them to the view that it must be of such origin. This view, furthermore, was supported by the fact that,

during the late war, only in 1/3 of the cases in which the diagnosis of dysentery was clinically confirmed were the known dysenteric organisms recovered. Among the observers supporting this opinion were Strausz, Leusden, Hurst and Schur.

Another group of investigators took a rather questioning attitude on the subject. On the one hand the fact that the dysentery bacillus was so infrequently found in ulcerative colitis and also the fact that the illness ran a course peculiarly its own inclined them to the belief that it had an etiology of its own. However, they did not consider this a sufficient criterion to support such a view. Moreover, these men considered it not unlikely that the cause of ulcerative colitis might be an unknown variant of the dysentery group of organisms. Strausberger and Udaondo were inclined to view the condition from that standpoint.

Rollaston took a different stand. He considered ulcerative colitis to be a non-specific disease and argued that various microorganisms might play a rôle in its production. He called it a *syndrome* in which the clinical findings were quite constant but in which the anatomical changes were markedly different. Boas, who named the disease "ulcerative colitis", was the first investigator to consider it as a clinical entity. In an article appearing in 1903, he called attention to the many points of difference existing between this condition and true dysentery.

At first there were few who agreed with Boas in this view but gradually others joined him in the belief that he was justified in separating ulcerative colitis from the dysentery group. One of his strongest supporters, Ad Schmidt, wrote an article in 1914 summarizing all the important reasons for considering ulcerative colitis a separate entity. Because of its cryptogenetic character, he advocated separating colitis from all those intestinal infections in which pathogenic organisms were known to be causative.

Zweig and Albu, among others, were of the opinion that ulcerative colitis was a separate and independent disease brought about by specific microorganisms. Many investigators who held this same view have searched for the true etiology but this work has always been very difficult because of the numerous bacteria present in the intestinal tract, saprophytes as well as pathogenic organisms. Further, the fact that

\*Submitted to the faculties of the National University at Groningen, in candidacy for the Degree of Doctor of Medicine, on the authority of the Rector Magnificus Dr. H. W. C. Bordewyk, Professor in the faculty of Jurisprudence. To be defended before the faculty of medicine on Wednesday, July 11th, 1934, at 4:00 o'clock in the afternoon.

†Courtesy of the Author and J. B. Wolter, Publishers Groningen, The Hague, Batavia, 1934.

Submitted for publication August 10, 1934.

in the study of a certain pathologic process, unless some specific organisms are present in large numbers, one cannot draw definite conclusions concerning the causation. It is also well known that many organisms, normally saprophytes, may assume pathogenic properties and thus cause disease. Bassler and Rosenheim have ascribed to the colon bacillus etiologic importance in this condition. They believe that the colon bacillus can become very virulent and, in their opinion, ulceration might result through the activities of the colon bacillus in association with a streptococcus.

Lockhart-Mummery is of the opinion that not only the colon bacillus and the streptococcus but also the diplococcus of pneumonia might be a causal agent. He reasons that the pneumococcus might be instrumental in causing the hemorrhagic type of ulcerative colitis. This pneumococcus infection he considered primary and not a complication of pneumonia. Many other organisms have been considered in a study of the etiology of colitis such as the streptococcus, gas bacillus, the *bacillus enteritidis* of Gärtner, the *bacillus proteus vulgaris* and the *bacillus pyocyaneus*.

Bargen held that the gram-positive, *diplo-streptococcus* which he isolated from the ulcers of patients with this disease was the etiologic factor. As we shall try to make clear in the following, we believe that on the basis of bacteriologic, clinical and experimental evidence, there is good ground for supporting Bargen's contention.

We have already mentioned the fact that, in 1903, Boas called this clinical entity "ulcerative colitis". Other observers, however, have objected to this term and have substituted others which they considered more typical of the condition. Ad Schmidt, because of the very frequent presence of pus in the majority of the cases, called it "colitis suppurativa." Friedel attempted to introduce the term "colitis hemorrhagica." Rosenheim chose the name "colitis ulcerosa gravis."

Not always, however, is there pus formation in colitis and in even serious cases it may be present in only very small amounts. Neither is the presence of hemorrhage a constant symptom. The name "colitis gravis" may often be correct but, on the other hand, many cases of colitis run a fairly benign course. Differences of opinion on the characteristics of the disease are thus shown in the variety of names which have been given to it. I rather feel that the original name "colitis ulcerosa" is fitting if one does not lose sight of the fact that ulcers appear only at certain stages of the pathologic process, while the additional word "chronic" must be considered in connection with the tendency of the disease often to show chronicity.

#### THE PURPOSE OF THE INVESTIGATION

As we have already mentioned, Bargen, of the Mayo Clinic, reported considerable work on the isolation of gram positive diplococci from ulcers of patients suffering with ulcerative colitis. On the basis of animal experimentation, he considered these organisms the cause of this disease and on this basis made autogenous vaccines with which he obtained excellent results in the treatment of his patients. This successful work led us to introduce vaccine therapy in the treatment of patients we saw at the Groningen Clinic.

#### CLINICAL SIGNS AND SYMPTOMS OF ULCERATIVE COLITIS

The picture of ulcerative colitis consists of a number of clinical symptoms of greater or lesser gravity,

depending on the seriousness of the intestinal disturbance and the stage of the disease. Efforts have been made to distinguish different clinical forms of the disease-process in harmony with certain symptoms, but this is not practical as the various manifestations are only evidences of *different stages* of the disease. It now is considered much more rational to think of these different stages as the result of *one disease process*. Only the most important symptoms will be considered in this paper.

#### SUBJECTIVE COMPLAINTS

Generally the patient complains of *pain* which may be felt over the entire abdomen, or only over certain areas. Frequently, the pain is located in the region of the sigmoid but it is not rare to have it quite definitely outlined over the entire colon. The pain, which varies a great deal in intensity, frequently becomes more intense and colicky before defecation. After the bowels move there is generally considerable relief. Udaondo attributes the colic to colon spasm. Frequently, in cases associated with meteorism, there is much colic and abdominal noise; here passage of flatus brings relief. In some patients there is marked tenesmus, which however, does not differ from that which is found with many other intestinal conditions. *Distention* often is a troublesome feature and is aggravated by movement. Rest in the dorsal position generally gives relief.

#### GENERAL CONDITIONS

The intestinal disturbances brought on by ulcerative colitis apparently do not always affect other bodily functions, so we may observe very few general symptoms. Generally, however, we do have some, depending upon the onset and violence of the infection. In the acute or sub-acute case there is more or less *rise in temperature* which may be intermittent or continuous, or according to Schmidt, may show a septic curve indicating a general infection. In those cases running a chronic course, the temperature is generally normal but associated, occasionally, with slight elevations indicating a lighting up of the disease process.

Even advanced departures from the normal colon, in long standing cases, are often accompanied with good general nutrition. Only slight pallor and the passage of mucus betray impaired health. However the majority of chronic cases show *weight loss*. The patient is exhausted and has an anxious expression. Changes in the intestinal excretions almost immediately are reflected in his general condition. When the diarrhea improves, either spontaneously or following treatment, the patient responds very quickly; he improves and takes on weight.

#### DISTURBANCES OF DEFECATION AND ABNORMALITIES OF THE FECES

The most common complaint is *diarrhea*. In considering this symptom one must differentiate between an "essential" and an "apparent" diarrhea. The latter, it must be remembered, continually exhibits evidence of some pathological products in the discharges. The passage of frequent stools in some cases is the only subjective symptom. The diarrhea may be of sudden onset leading one to a diagnosis of "acute catarrhal gastro-enteritis". Later, other evidences of ulcerative colitis appear. Sometimes periods of apparent well-being alternate with periods of diarrhea. The picture may be a very innocent one until the

Fig. 1. Normal mucosal foldings.

Fig. 2 A. Section of transverse colon with coarse transverse folds; longitudinal folds entirely absent. Descending colon and sigmoid colon show honey-comb structure.

Fig. 2 A.

Fig. 2 B.

Fig. 2 B. Coarse transverse folds; longitudinal folds missing.

appearance of sanguino-purulent feces betrays its seriousness. Albu reports the onset to be such in the majority of his cases. The stools may number nine to ten daily but may go to fifteen or twenty. The location of the lesions has considerable influence on the number of evacuations. In involvement of the lower end of the colon, tenderness and frequent urge to defecate are common, although very little fecal matter is expelled. Udaonda declares it not unusual in such cases to find a persistent obstipation even though there is a frequent desire to defecate. This so-called diarrhea is then a misnomer.

### THE FECES

In most cases the expelled material consists only of pathological substances, such as blood, mucus, and pus, containing very small amounts of fecal matter. In those cases in which the lesions are localized in the upper part of the colon, the stools are thin and of soup-like consistency. Pus, mucus and blood in their passage down becomes more intimately mixed with the intestinal contents and may undergo various changes. Only when they pass through the bowel rapidly are they found as such in the feces. On the other hand, in a recto-sigmoiditis, these abnormal constituents are not mixed with feces at all. The presence of pus in the stool, according to Udaonda and Schmidt, is the most characteristic and constant finding. According to these observers, it is always found if persistently looked for. Pus in very small amounts may be intimately mixed with feces and its detection even with the microscope is, in such cases, not easy, however, its finding is of such fundamental importance that it is very necessary in all stages of the illness even during convalescence. Also, where blood is present in quantity as in the "hemorrhagic form" of colitis, the presence of pus may easily escape detection. Albu maintains that the presence of pus in the stools is not a constant symptom in ulcerative colitis. In many of his patients he could not demonstrate it. This agrees with our experience as we often search for pus in vain. But in patients with demonstrable ulceration, pus is always present. Microscopic confirmation of this finding is absolutely necessary inasmuch as mucus may resemble pus, macroscopically. It is particularly in the acute catarrhal stage of ulcerative colitis that stools may consist largely of blood, and blood loss may be large. When improvement follows, macroscopic blood disappears rapidly, although the frequency and contents of the evacuations may still be quite abnormal. For long periods, blood can be shown spectroscopically. It is sometimes quite remarkable how well patients may appear even after losing large quantities of blood. Mucus is present in both mild and severe cases. In the acute stage, it often is entirely absent.

The stool generally is weakly alkaline in a well established case. Auba, Schmidt, and Lohrsch frequently found eosinophile cells and also Charcot-Leyden crystals.

### PHYSICAL EXAMINATION

The abdomen of a patient with ulcerative colitis may be of normal contour but may be, as a result of meteorism, quite distended. Usually, however, it is flat or even retracted. If the abdominal wall is soft and allows deep palpation, one often may palpate certain parts of the colon, contracted and slipping away from the examining fingers. The descending colon and

the sigmoid, are very often palpable, inasmuch as the disease process is there generally localized. In severe cases, abdominal distention prevents deep palpation. If one is fortunate and able to overcome this difficulty, one finds the entire colon extremely sensitive to pressure. The distention and the pain which palpation elicits, are probably the result of a pericolicitis of an inflammatory character. In those cases which exhibit a febrile course, with toxic manifestations, very often a slight swelling of the spleen can be demonstrated.

### EXAMINATION OF THE RECTUM

Digital examination of the rectum is of the utmost importance, because it may reveal conditions such as polyps or carcinoma, which often present symptoms strikingly similar to those of ulcerative colitis. Rankin, Bagen and Buie, give a careful account of their experiences in this connection. Generally, the rectal sphincter is spastically contracted and introduction of the examining finger is often difficult and painful. The most satisfactory position is the knee-elbow. The buttocks are separated and the vaseline-coated finger introduced at full length with the palmar aspect toward the bladder after which the finger is carefully rotated about 180° and pushed in the direction of the *plica rectosigmoidea*.

In the early cases of ulcerative colitis, the mucosa feels slightly roughened and one gets the impression of palpating a velvety surface. In later stages of the disease, one meets with irregularities, such as slight elevations on an otherwise smooth surface. If narrowing has taken place in the rectum, this is easily felt and one can generally outline the nature and extent of the stricture; withdrawal of the palpating finger often reveals blood, mucus and pus.

### BLOOD PICTURE

The blood examination seldom gives any characteristic findings. A lowered hemoglobin content is often shown. The anemia, however, is generally mild. A hemoglobin estimation of 28%, as reported by Udaonda, is an exception. In cases with much blood loss, the erythrocytes may show marked falling off. A slight leucocytosis ranging from eight to fifteen thousand is often present. Differential count is not particularly abnormal. Anemia sometimes met with in severe, long-standing chronic cases of ulcerative colitis, often is accompanied with marked cachexia. However, as autopsy has taught us, a wrong interpretation of this sign may lead to a diagnosis of carcinoma.

### PROCTOSCOPIC EXAMINATION

This method of examination also is necessary for the differential diagnosis of those conditions which are detected only by visual examination. If circumstances permit, it is desirable to make proctoscopic examinations at frequent intervals during the entire course of the illness. In this manner, one is enabled to visualize the various changes in the mucosa, particularly in the rectum and sigmoid and also to determine whether a temporary improvement in the general condition of the patient is associated with actual healing of the lesions. If, in spite of clinical improvement, the local lesions remain unchanged, we know it is only apparent and not real. In the presence of a recto-sigmoiditis, such examinations are always painful and a local anesthetic is necessary. Ordinarily a two to ten per cent solution of cocaine or novocain is used.

Udaondo describes the various pictures seen with the procto-sigmoidoscope. These differ markedly depending on the stage of the disease and the gravity of the illness.

In an *acute case*, the mucosa of the rectum and sigmoid is hyperemic and dark red. Here and there, submucous hemorrhages are seen. These are smaller or larger and even careful instrumentation may easily cause bleeding into the bowel. In the more advanced cases the mucosa is swollen and edematous, has a violet color, and appears shiny. Later, small miliary abscesses develop which form slight elevations. These are easily confused with lymph-follicles diffusely spread throughout the diseased areas. Rupture of these abscesses brings a discharge of pus and, as a result, small shallow ulcers develop, often punctate in character. Unless one observes carefully, these can easily be overlooked. They are better recognized if the mucous surface is first cleaned by a gauze applicator.

One then observes the miliary ulcers as small red points on a background of hyperemic mucous membrane. Some ulcers may be somewhat larger but always they are shallow.

In some areas the ulcers may be confluent, resulting in a larger ulcer with irregular borders. The grayish base of these shallow lesions is covered with mucopurulent material which is removed with difficulty. The lesions are always several centimeters above the sphincter and are not found in that region. In the upper part of the rectum and the distal part of the sigmoid, we generally find the most marked involvement. The mucosa adjoining the ulcerated areas is as a rule much paler than normal or in the ulcerated segments.

In *chronic cases* which have had periods of remission and exacerbation, secondary infection often is present. One then sees shallow areas of relatively large size, (1-3 cm. in diameter-Buie) with irregular borders. These are very resistant to treatment, local as well as general.

In the *healing stage*, Udaondo noted, first a disappearance of the hyperemia. The mucosa becomes paler, the swelling subsides and ulcers gradually disappear. If this takes place slowly, small lesions may remain which later become the starting point of a subsequent exacerbation. On the other hand, in the more serious cases there is a constant tendency for the lesions to become confluent; such may cover a considerable surface of the involved area. Two cases have been reported in which the process had spread over the entire rectal mucous membrane.

#### ROENTGENOGRAPHY

In general, the symptomatology combined with procto-sigmoidoscopic and laboratory findings, will enable one to make a diagnosis of ulcerative colitis. One must, of course, remember that other conditions, as polyposis and malignant disease may display the same findings. However, a better insight into the actual disease-process calls for roentgen ray examination, inasmuch as this enables one to determine the location and spread of the lesions. This method of examination does not differentiate the lesions from those of other infections such as tuberculosis or chronic dysentery which cause similar pathological-anatomical changes, and which macroscopically resemble the ulcers of ulcerative colitis.

#### REMARKS ON TECHNIQUE

In order to make a satisfactory roentgen examination, thorough cleansing of the bowel must be carried out. In those cases with chronic obstipation, a laxative is necessary. In the others, laxatives are not used because of a possible irritation of the mucous membrane during examination. The evening before the day of examination, the patient is given a warm water enema of 1½ liters and is allowed a bowl of thin cereal for supper. The following morning nothing is given by mouth. Three hours before the examination, another warm water enema of 1½ liters is given. We may assume that in this three-hour interval between the enema and the introduction of the contrast mass, the water not expelled is completely absorbed.

As a contrast medium, we use a barium mixture, at least, when we desire a picture of the filled bowel. In those cases in which we especially wish to study the mucosa, "umbrathor" is preferred. This preparation, similar to "thordial", gives better details of mucosal conditions than do barium preparations.

Two methods of giving the contrast mass are open to us, *per os* or *per rectum*. Inasmuch as the oral method alone is not satisfactory, some observers use a combination of the two in order that a better study can be made of the upper part of the large gut.

We have been using only the rectal method. For a more exact study of the involved bowel it is advisable to control the introduction of the barium enema with the fluoroscope. In cases of ulcerative colitis, X-ray films show very marked differences depending on the stages of the illness and the chronicity of the case. Roentgenologically, therefore, one is justified in dividing the course of the illness into different stages. Knothe mentions an ulcerative, a nodular hyperplastic and a healing stage; however, at autopsy one often finds no ulceration in cases which ran a severe course. Thus, Polak Daniel reports a case in which, because of a long-standing colitis, resection of a large segment of the colon was done. The patient died immediately following the operation. At autopsy, no ulcers were found either in the resected part or in the remaining portion. It, therefore, seems wise in our opinion to add a fourth, namely, a catarrhal stage.

#### THE CATARRHAL STAGE

In the stage, in which only the superficial mucosa is affected, we do not always find on using a contrast mass that there are departures from the normal. Nevertheless, at this time the function is disturbed to a much greater degree than the pathology would indicate. The gut already manifests excessive irritability. If the rectum is involved, the barium mass may immediately be expelled by the patient unless by great effort he manages to retain it. At the time one is ready to take the picture, the rectum may be entirely empty and only the segment of the colon above the *plica rectosigmoidica* is filled with the barium. In such cases, however, the rectum may show a characteristic picture. The ampulla is narrow and enough contrast mass remains attached to the walls to enable one to see the contour and linear configurations can be made out between the folds of the markedly indurated *ampulla recti* where the barium has been retained. This irritability, which is a result of the infection of the superficial mucosa, can also manifest itself in other parts of the colon. Spasm can quickly bring about a

Fig. 11.

narrowing of the gut anywhere, thereby, producing the picture of a narrow band. Haustration may completely disappear, thereby, giving the bowel the form of a tube with walls evenly distant from each other. This picture is in decided contrast to that of spastic obstipation in which haustration is the characteristic feature.

The irritability of the affected portion of the gut is also responsible for the fact as described by Stierlin, that the shadow of the contrast mass in the normal segments of the bowel is much more intensive than in the diseased portion. In the otherwise normally filled colon, the affected part appears to have "dropped out." This phenomenon was originally described by Stierlin in cecum tuberculosis. In this condition, after oral administration of barium, the tuberculosus cecum appeared only as a vague shadow. The explanation is that the hypermotility forces the barium through the affected part so rapidly that it does not have time to fill properly. This hypermotility has been observed in non-tuberculous states and in other portions of the bowel. The above described manifestations of irritability often are very difficult properly to evaluate. They should not be confused with the spasm that develops in any normal bowel following the introduction of the contrast mass, which spasm soon subsides. For this reason, it is important to get an idea of the character and behavior of the mucosa in the early stages of ulcerative colitis, perhaps more so than in the later stages. Knothe points to the great value which the study of an x-ray film will give early in the course of the process.

In order to accomplish this, it is necessary to evacuate the barium mass from the colon after the radiographic examination. Usually, in the catarrhal stage of ulcerative colitis this is easy because of the hypermotility of the bowel. When sufficiently empty and the intestinal walls approximate each other, enough barium remains attached to enable one to visualize the mucous folds and the spaces between them.

When we study the roentgen film we find marked changes in the contour of the intestinal folds. The longitudinal folds disappear but the transverse are more prominent. These changes are brought about by the swelling of the mucosa and the disturbed function of the *muscularis*, inasmuch as this contracts only in these areas which are not affected. Apparently the catarrhal stage may exist for a long time without necessarily causing a change for the worse. However, in those cases becoming more seriously involved, the swelling increases and the mucosal surfaces undergo a complete change. The *muscularis* is affected to such a degree that folding is no longer possible. The *mucosa* then forms, as it were, a series of pouches into the lumen of the gut, with crypts in between. All pliability has now been destroyed and we have a rather rigid tube-like structure which shows a honeycomb texture on the radiographic film.

#### ULCERATIVE STAGE

Knothe assumes that these crypts found in the catarrhal stage are the sites of potential ulcers. In cases where there is little or no tendency to healing, these crypts become larger and deeper and begin to ulcerate. Then we have the picture of a true ulcerative colitis. Subsequently, the deeper layers of the bowel become involved resulting in serious disturbance of function. So now we no longer have a thin

walled, pliable and elastic colon but a narrow, rather rigid tube with thick walls. Haustration and other movements are absent. At the same time, there is a tendency to shrinking and shortening, particularly of the descending and sigmoid colons. Even with complete filling these segments may remain narrow and shortened. (*Corde Colique*, Friedel). The picture described can never be mistaken and when once seen will enable one to make a correct diagnosis at once. Bargen and Weber have compared this appearance of the bowel, very fittingly, with a sclerotic blood vessel.

In this connection, however, we must consider the important part which nervous disturbances sometimes play in bringing about pictures of this kind. Repeatedly, one sees in mild cases that the roentgen picture again becomes entirely normal, which one should hardly consider possible if the roentgenologically demonstrated departures from the normal are based entirely on pathologico-anatomical changes. In this connection, let us consider the following case:

A farmer, aged twenty-three, was admitted to the Clinic at Groningen, in March, 1923. He had suffered for nine years with a persistent diarrhea, the onset of which had been rather mild. Intervals of more or less frequent diarrhea were common. Before each movement there was a painful urge, at times so severe that he had difficulty in getting to the toilet. There was much intestinal rumbling. For several months before admittance he had been growing worse. He complained of much fatigue and was greatly emaciated. A few weeks before admittance he had vomited three days in succession. The stools were generally thin and always slimy, frequently bloody, and had a foul odor. The general nutrition was poor. Pulse was within normal limits. Blood pressure 100-70. Heart and lungs normal. Outside of a little tenderness along the descending colon, the external examination of the abdomen was negative.

In the rectum, about 10 cm. from the anus, the finger met a complete stricture. This was confirmed by rectoscopy. The rectal mucosa, however, appeared quite normal and the surrounding tissue showed no induration. Radiological examinations showed the barium given by mouth to have reached the cecum in six hours. Films of the colon revealed the picture of a stiff tube without haustration. A few areas were markedly contracted. The rectal stricture was not seen.

During the first few days of his stay at the Clinic, he defecated about six to eight times daily. Diagnosis of colitis was made and appendicostomy was decided upon in order that colon irrigations might be carried out. For a long time, tannin solution (1%) was used with no improvement, so it was decided to put the entire colon at rest by instituting an artificial anus (ileostomy).

At operation, the cecum and entire colon appeared pale and felt indurated. The distal part of the cecum was also pale and rather more contracted than the remainder of the small bowel. Tannin irrigations were again instituted and the rectal stricture was stretched. Three months later the x-ray picture had not changed and the stricture was still complete. It was then decided to connect the transverse colon to the pelvic colon beyond the stricture. This attempt failed because of the rigidity and immobility of the involved bowel. In order, therefore, to restore the appendicostomy, a side to side anastomosis between the cecum and ileum was attempted. However, infection developed and death followed.

At autopsy, the small bowel revealed no abnormalities. The cecum and ascending colon were somewhat distended. The transverse colon, descending colon, and sigmoid were collapsed. There was a little thick, cloudy, yellowish fluid in the bowel. There was no narrowing at the splenic flexure or at any point below. No resistance was met at

the site of the assumed stricture. The mucosa of both colon and rectum was smooth and revealed no defects or any evidence of hyperemia. Microscopic examination made clear that the site of the clinical stenosis showed a normal intestinal wall slightly contracted in some areas. The mucosa was normal. There was no evidence anywhere of inflammation, except the peritoneal exudate found on the serous surface. The pathologist, therefore, assumed that we were dealing with a condition involving a neuropathological background.

In the film of the *ulcerated bowel*, filled with a contrast mass, the contour of the shadow differs greatly. Often it is smooth. In other instances, it may have a feathery appearance or perhaps look moth eaten. The borders may, at times, have a saw-toothed appearance. In radiographs which give one the impression of containing crypts, Bergen and Weber assume that the process is submucous. Such a case came to our attention in a patient who died two weeks after this phenomenon was observed. At autopsy no ulcers were found. Just how much ulcers are responsible for the shadow or how much the appearance is due to contraction of the *muscularis* is not clear. Sometimes a film would show a smooth contour, while on a subsequent exposure of the same case, the aspect was irregular. From the foregoing, it seems that the radiogram of the non-ulcerated bowel, as well as the ulcerated one, may show irregular borders. And inasmuch as the contour of the ulcerated gut may be perfectly smooth, it is safe to say that the film of the barium-filled bowel for the diagnosis of ulcer, is not always to be relied upon. Hence, it is necessary to rely on other roentgenological findings for determining the presence or absence of ulceration.

Regardless of whether we accept Knothe's theory about the ulcers originating in crypts or whether they were originally abscess cavities (Buie), the question arises how can we distinguish typical ulcerations on the radiograph. This problem led us to take the colon from a subject who died with a suspicion of having ulcers and treating it as we would *in vivo* in order to get a better understanding of the appearance of ulcer on the x-ray film. After this specimen was thoroughly rinsed with water, it was filled with "umbrathor." This was then poured out and a picture taken. On this film, plainly were seen circumscribed spotted areas. Some of these were surrounded by circular shadows, others by (Fig. 10 and 11) irregular shadows. On opening the gut the configuration seen on the film proved to be as far as location, form, and size was concerned, the site of ulcers (Fig. 12 and 13). The more deeply shadowed borders corresponded to the edges of the ulcers. On cutting open the entire specimen, it was found that the only ulcerated areas present, were those which we had considered as being such. However, one cannot interpret these shadows as ulcers without some reservations. Figure 14 shows the radiogram of a patient with mild obstipation. The marked areas, with rather deeply shadowed borders, are plainly seen. However, neither after introducing air nor on a film taken three weeks later were these figures seen again. Most likely they were shadows of haustra taken tangentially. If, indeed, ulcers were present they might be seen in a radiogram taken according to Fischer's method. For a correct opinion, therefore it is necessary that, after a short time has elapsed, another film be taken or that the examination be made complete by using Fischer's technique.

## THE NODULAR HYPERPLASTIC STAGE

In cases of deep ulceration which is widespread, the tendency to healing is shown by the gradual disappearance of the ulcers and the associated submucous pathology. If the radiogram is then examined, we find a nodular aspect developing. These nodules represent remnants of the remaining islands of infiltrated, swollen, and hyperplastic mucosa. (Fig. 15). Each exacerbation of ulcerative colitis should present this picture and one can, therefore, decide from the picture that the final stage is present if taken in consideration with the findings of the second or ulcerative stage. If on the other hand, the case is of many years' standing, it becomes very difficult to determine whether the condition is one of true healing or is a recurrence of the trouble. The course of the healing-process in the mucosa determines to a great extent the final condition. In the most favorable cases after many months, one finds the coarser, nodular appearances changed to a rather fine, even, speckled appearance of the entire bowel.

## THE HEALING STAGE

As healing progresses, the "nodules" become fewer, intestinal folds again appear and gradually become more visible and after a period of months the mucous membrane may again assume a normal aspect. Bergen is of the opinion that the healing stage is accompanied by the growth of new mucosal structure over the remaining "islands" of the old healing bowel. There is, however, still another possibility, that is, that the new mucosa may regenerate to the borders of the islands with the result that these may be more or less forced into the lumen of the bowel. We must bear in mind the fact that these "rests" may be the starting points of polyps which may grow to considerable size. The number of these may be great, depending on the extent and severity of the colitis. Polyposis, arising in this manner, sometimes is called "pseudopolyposis"; the roentgenogram strikingly resembles that of true polyposis.

In both, the coarse markings of the mucosal shadows are striking and haustration is absent. Both conditions may show the same irregularity of the bowel contour.

Information on the actual condition of the mucosa in these cases is not confined to a study of the intestinal folds. One can also use the *method of Fischer*, in which, after the expulsion of the contrast enema, air is introduced into the bowel and films then taken. This method requires great care because in the presence of ulcers or spasm excessive pressure immediately causes intense colic. In cases with ulceration the films now taken will reveal a rather spotted or marbled appearance of the bowel instead of that which one sees after expulsion of the barium. Sometimes the films give the impression of a braided band. The contrast mass then attached to the inner wall of the bowel resembles trellis work. (Fig. 20). Schinz points out that these spots only in part resemble shadows of ulcers. The greater number, he thinks, are shadows of the contrast mass adhering to the mucosa of the bowel wall. Schwarz and Novascinsky found, in cases coming to operation, only few ulcers in bowels showing this peculiar marbled appearance on the x-ray films. Literature on the subject warns against placing too much importance on the value of these peculiar markings in diagnosis because films of the normal colon may reveal like pictures. We have seen this

marbled appearance in a patient who was thought to have ulcerative colitis but at autopsy not one ulcer was found in the entire colon. Apparently then, films taken by Fischer's method show nothing that is specific in the differential diagnosis of the catarrhal or the ulcerative stages of ulcerative colitis.

In order to arrive at a better understanding of this problem we undertook the application of Fischer's method to a section of the bowel from the cadaver mentioned before. After filling the gut with air, films revealed irregular figures of which the border shadows were markedly outstanding. These figures as far as localization, form and size are concerned agreed entirely with the ulcers present. In the same manner, all the existing ulcers could be recognized. Figures 21-22 will show this better than a description. There is, therefore, support for the contention that it is possible, following Fischer's method, to differentiate between true ulceration and those shadows resulting from areas of remaining contrast mass adhering to the bowel wall.

Hammer carried out analogous experiments. He used a barium combination. In many instances, he was able to recognize ulcers which were located on the borders of the shadow. However, those present on the anterior and posterior aspect, he was only occasionally able to identify, probably because of the direction of the rays. In ulcerations involving the ileocecal valve, insufficiency or even a stenosis may result. In the former, an enema of contrast material may pass through into the ileum. In the latter, a barium meal may stagnate in the small bowel. Valve insufficiency may, to a certain degree, be functional, for we have seen it occur in the catarrhal stage and on recovery found the valve again competent. Moreover, we must remember that in exceptional cases the barium enema may pass through the valve entirely in the absence of colitis.

#### LOCATION OF LESIONS IN ULCERATIVE COLITIS

As a rule, only a portion of the colon is involved in ulcerative colitis. The usual beginning localization is in the sigmoid colon and the rectum. Barger and Weber declare this is the favorite area for its development. The process may be limited to this region but may spread to any part of the colon. These observers maintain that 20% of all cases are found there. In few cases are cecum and ascending colon involved. In such, the spread is toward the hepatic flexure and the transverse colon. Wolvius and Udaondo report that in those cases with involvement of the transverse colon, pain frequently is worse at night. These patients have severe abdominal pain, palpitation, sweats, and give one the impression of being seriously ill.

#### GENERAL CONSIDERATION OF TREATMENT IN ULCERATIVE COLITIS

During the period when acute symptoms are present rest in bed is absolutely necessary. Later, with a normal temperature, when the bowel movements have dropped to one or two daily, and the contents show few or no pathological elements, the patient may gradually be allowed more freedom. A very careful regime, however, is imperative and several hours of rest should be taken daily. The x-ray findings are evidence of the fact that true healing does not always accompany a disappearance of clinical symptoms. The fact that complete restoration of the bowel may be

slow is evidenced by the experience that irrigations through a cecostomy must, in some cases, be carried out for a year. Next to physical, mental rest is of the utmost importance. The old saying that "affections of organs above the diaphragm tend to optimism and those below to pessimism" is well exemplified in ulcerative colitis. One needs, therefore, to encourage the sufferer and to put his mind at ease as far as possible. All remedies which are useful for this purpose are indicated. Weather permitting, an outdoor regime is very desirable. Sunlight and ultra-violet rays have been considered to have favorable influences. For good results, Udaondo claims it is necessary to give exposures sufficient to bring on a reaction associated with erythema and desquamation. Warm applications to the abdomen often relieve colic and are always appreciated. Electric pads can be used if desired.

#### DIETARY MANAGEMENT

From our present conception of ulcerative colitis, it is apparent that, in times past, we have been constructing our diet along too rigid lines and as a result benefits of the dietary measures hardly made up for the many complaints to which they gave rise. In recent times, we have come to realize more than ever that the colon is largely a storehouse for substances which later are expelled. It is true that in the proximal part of the large bowel some absorption takes place but the digestible substances of the food are mainly digested and absorbed in the small intestine. Rigid and arbitrary diets are not prescribed any more. Nevertheless, it is necessary to take certain precautions in feeding colitis patients.

The food taken should be such that it does not cause the least irritation of the colon. We, therefore, preferably advise food that is for the most part rather well absorbed in the small gut, leaving a minimum of residue. Vegetables containing much cellulose even when given as puree, fresh bread and fruits are not generally indicated. Boas advises a diet containing very little roughage. Udaondo is more lenient and allows, for instance, such dishes as *compotes*. Further, it is necessary that the food in question contains sufficient vitamins and has the required caloric value. The proper choice of food used in arranging the diet will generally take care of the vitamin needs. Larimore points out that the action of the vitamins in connection with the whole process must not be underestimated. If we wish to increase these, it is easily done by adding orange, tomato and grape juices. Other vitamin-rich foods can be prescribed.

In order to arrange the proper foods in an appetizing way, it is necessary that the patient take a sufficient number of calories dependent, of course, upon his body weight. For liquids, one may use boiled water to which a little cognac has been added, weak tea, cocoa, camomile tea and small quantities of red wine. Proteins can be supplied in the early stages of the disease by using fresh fish and rare done meat. Depending upon the tolerance of the patient for different types of food these general rules can be modified. Keeping these in mind, we can later prescribe diets which we consider entirely satisfactory for the general nutrition of the patient and at the same time harmonizing with our present ideas of proper feeding in colitis.

Rankin, Barger and Buie do not favor frequent feedings in the acute stage. Their reason is that every feeding initiates peristaltic movements which may

Fig. 26.

---

Fig. 27. Area indicated by the dotted lines has appearance of ulcer. Post-mortem this shadow proved to be a calculus in the left kidney.

---

give rise to more frequent defecation and even to bleeding. Milk is not advised particularly when there is much diarrhea and flatulence because it is not tolerated very well and leaves considerable residue. Other milk products such as kephir, yoghurt and cheese are allowed.

Diet in the presence of obstipation will be considered presently. In those cases in which there is a tendency to diarrhea, liquid diets are more or less restricted. Schmidt and Noorden begin their treatment of acute colitis and its exacerbations by fasting the patient two days. During this time they give only weak tea and small quantities of red wine. This induces rest for the intestinal tract which usually is followed by some improvement. An acceptable diet is then prescribed. Udaondo begins dietary treatment in the acute stage by giving gruels with a little sugar, mashed potatoes, rice and macaroni. We are giving here a diet scheme which was originated by Rankin. Inasmuch as American diet and food habits differ somewhat from ours, we have made some necessary changes which make it more suitable for us in Holland or on the Continent.

Useful laxatives are magnesium sulphate ( $\frac{1}{2}$  tsp. in warm water every 15 minutes until bowels move) liquid paraffin, castor oil and senna preparations. Very frequently relief of the colon spasm is sufficient to overcome obstipation. For this purpose one could use, with satisfactory results, one of the following agents: Sulphate of atrophine subcutaneously 1 mgr. daily; tincture of belladonna, 20 or 30 drops daily; papaverine, pure .06 grams daily.

#### ORAL MEDICATION

Opium and belladonna preparations. In order to give an ulcerated bowel sufficient rest and to relieve pain in serious cases, opium and belladonna preparations must be used. Bensaude praises the use of bismuth in the form of sub-nitrate or of magisterium-bismuth. In cases with much diarrhea, he does not give the latter more than 1 gram, 4 times a day. This decreases peristaltic action while larger amounts have a laxative effect. The favorable effect of bismuth preparations is attributed to the protective and astringent effect which they have on the mucous membrane. They further are assumed to have an anti-

| sugar if desired                  | Custards and lemon pudding        |                                     |
|                                   | Coffee or tea with cream or sugar |                                     |
|                                   | if desired                        |                                     |

#### ADDITIONAL FOODS:

(1) Ripe banana, (2) Orange juice-100 grams, (3) 100 grams cream in coffee or tea, (4) Small bowl of vegetable soup, (5) A baked apple without skin, stewed apricots, pears or peaches, applesauce, (6) Small bowl tomato soup, (7) Puree of young carrots, beets, asparagus, spinach or shelled peas.

*Remarks:* These additional foods may gradually be added to the prescribed diet as soon as the condition of the patient allows. Jelly and jam are permitted. Spices and condiments are always forbidden. Fluids should not be taken while ice cold. Nothing is taken between meals in order to prevent unnecessary peristaltic movements.

#### TREATMENT OF OBSTIPATION:

If the patient is inclined to obstipation, this demands treatment inasmuch as masses of feces passing through the ulcerated area might exert a harmful influence. To combat this complication one should keep in mind rather not to use food which has any astringent action. In case diet alone does not bring desired results, one must resort to enemas or mild cathartics. Enemas should not be given with much pressure. The amount of the injected solutions should not be greater than one liter, inasmuch as the capacity of the ulcerated bowel is markedly reduced. Physiological salt solutions, liquid paraffin and camomile tea are well suited for this purpose. Solutions containing soap or glycerine, however, are not advisable because of their irritating qualities.

epic action and also to reduce the irritability of the bowel. The absorbent and anti-fermentative action of this preparation also relieves meteorism. Inasmuch as bismuth changes the reaction of sulphuretted hydrogen, it greatly reduces foetor. If stenosis is present, however, it is necessary to use care in giving bismuth for long periods of time because of its toxic effect; otherwise it can be given for long periods of time without danger.

Other absorbent remedies are sometimes used. Kaolin, animal charcoal, and norit are often useful. Astringent medicines if desired are tannin and "tannalbin"; of the latter we give from 3 to 6 grams daily. The use of astringent remedies, however, according to Udaondo, may result in a spastic type of obstipation which has a damaging influence on the inflammatory process in the colon. (Smithies employs subgallate of bismuth, a preparation readily forming a colloidal suspension—4 to 8 grams after each bowel movement) A. J. B.

Schottmüller advises *ferrum reductum*. He gives 4 to 6 grams daily. Others advise the use of gentian violet giving a 1 to 1000 solution in increasing doses of 3 to 5 up to 3 to 50 cc. daily and then gradually reducing the dose. Logan gives iodine, assuming that leukocytosis is produced. Haskell and Cantarow give calcium and para-thyroid preparations because of the finding that in ulcerative colitis the calcium content of the tissue is increased at the expense of the calcium in the blood. Cain and Lièvre treated a case of ulcera-

---

Fig. 29.

tive colitis with liver extract, which resulted in rapid improvement. The clinical condition in this patient resembled that of pernicious anemia but the blood picture did not, which led them to exclude this type of anemia.

With achlorhydria, hydrochloric acid is used. The absence of pepsin in the gastric juice calls for the administration of this preparation along with the acid. Indications of any serious anemia promptly disappeared with the use of *ferrum reductum* in our cases.

### MEDICATION PER RECTUM

Rectal medication can be given in the form of medicated clysmata, powders or suppositories. Solutions introduced in this manner should not be irritating. In order to overcome this, it is desirable to have them at body temperature. They should be preceded by a cleansing enema, the amount of which should not be over 300 cc. Enemas containing 2% boric acid solution, potassium permanganate, ichthyol, bismuth carbonate,  $\frac{1}{2}$  of 1% silver nitrate, protargol and camomile have been advised, but in most cases have been abandoned. Strong arguments against the use of some of these remedies have been advanced. In recent times much has been expected from the use of "dermatol" (5%) in oil of sesame. This is given in the evening after a cleansing enema and should be retained through the night. Other agents which have recently been used are 1% yatren (Schneck), hydrogen peroxide, tripaflavine, tannic acid 1 to 1000 and *bolus alba*. Udaondo, Centeno and Pinido advise acriflavine 1 to 4000. They give 750 cc. twice daily, this to be retained 15 to 30 minutes. After a week or two, when fever and diarrhea have subsided, it is used once daily. If improvement follows, this is then changed to 1 to 2000 solution of bicarbonate of soda and later to a 10% ichthyol solution.

In case the ulcers can be reached rectoscopically, local medication with powders may be instituted. Albu and others favor this method. Before introduction of the instrument, which must be done very carefully, it is necessary to use a cleansing enema of soda bicarbonate. The rectoscope is then introduced and medication applied directly to the ulcers. Agents frequently used for this purpose are "dermatol" 50 parts, tannic acid and sodium chloride of each 5 parts, or talcum 10 parts with "dermatol" or "xeroform" 5 parts. In case there is much tendency to bleeding, suprarenin can be added, or if severe pain is present, orthoform can be used. Preceding such treatments tincture of opium may be given *per os* in order to quiet any tendency to defecation and to favor the action of the local treatments. Such treatments should not be given oftener than every two days.

Suppositories are particularly indicated when there is inflammation in lower part of rectum frequently associated with painful tenesmus. Wolvius advises suppositories containing ichthyol 0.2, extract belladonna 0.03, dilaudid 0.003, ol. cacao 2; or balsam peru 0.150, extract hamamelis 0.030, chloret calc. 0.050. There is still to mention the treatment of Felsen who introduces oxygen into the rectum daily. In this manner he attempts to counteract the effect of organisms of decomposition.

### OTHER METHODS OF TREATMENT

Schur advised subcutaneous injections of emetine hydrochlorate 3 times daily in doses of 0.02 grams. Intramuscularly milk and yatren casein have been

used. Rachwalsky, Bucking, Boas, Hensle and also Hulst and Hartog saw improvement with the use of blood transfusions of 300 to 500 cc. Often one transfusion was sufficient, but in other cases, two or three were necessary. Strausz was not enthusiastic about the use of transfusions as he observed cases treated in this way who developed relapses. Von Bergmann considers that ulcerative colitis may be a functional disturbance in which sensitization plays a greater or lesser role. He is not an exponent of surgical treatment and doubts very much the value of irrigations with disinfectants such as "rivanol," yatren and other substances. This hypothesis of Von Bergmann led him to advise a treatment which was used in several cases of ulcerative colitis by Kalk. These patients were at first sensitized with an intramuscular injection of horse serum. This was repeated in from 12 to 20 days. If anaphylactic shock remained absent, a third injection was given intravenously. In cases treated later, the use of horse serum was abandoned and an attempt was made to produce a chill with blood transfusions.

Von Bergmann admits that this method is not without danger inasmuch as one cannot control the severity of the reaction. He, therefore, uses a method entailing less risk. In this, the patients are given 20 cc. of horse serum intramuscularly and 12 to 20 days later a rectal enema of 200 cc. of serum. If no reaction follows, he again gives the intramuscular injection and later if necessary the intravenous injection. In many cases of serious ulcerative colitis, he declares that by using enemas of horse serum regularly the widespread ulcerated areas would absorb enough serum-albumin to cause a reaction. If successful, this happens directly after the shock. Frequently diarrhea and the production of mucous and blood cease.

However, he does not consider that the disappearance of symptoms indicates a cure but is of the opinion that the mucous membrane should now gradually restore itself. In this book "Functional Pathology" he finishes his remarks on this type of treatment with the comment that one shock treatment seldom appears to bring results and that usually relapses occur which are not so favorably influenced by the treatment after the first time.

Hurst advises therapy which is very similar to that of Von Bergmann. He gives daily intravenous injections of 40, 60, 80, or 100 cc. of polyvalent dysentery serum and considers this treatment to be a non-specific albumen reaction.

### OPERATIVE TREATMENT

In spite of the fact that the armamentarium of the internist contains many possibilities in the attack on ulcerative colitis, one must frequently confess his inability successfully to cope with the disease and must send the patient to the surgeon. Often treatment of severe cases is not in the least successful and the patient loses ground in spite of all effort and seems doomed. In such cases one has the choice of the following surgical procedures:

1. *Appendicostomy*: In this operation the appendix is attached to the abdominal wall and opened. One is thus enabled to institute direct irrigations of the diseased bowel in the direction of peristalsis. In such cases a cannula is introduced into the rectum. The same astringents and disinfectants which are used in rectal irrigations can also be used for this purpose.

The toxic and infectious products are in this manner carried away much more satisfactorily and the ulcerated areas are reached more frequently than by rectal irrigations. A much advised method of cleansing the colon is that in which the drop method is used for a period of several hours. This solution, of course, can be medicated.

Such treatment is not very severe and for the patient the least troublesome of all surgical methods inasmuch as no intestinal contents flow into the artificial opening. It has also this advantage that it can very well be carried out at home. Against this method is the argument that the diseased intestine receives no rest which is probably the reason that this operation often does not bring the desired results.

2. *Cecostomy*: This operation can be done according to the Witzel technique or an ordinary cecal fistula can be made. In this way a portion of the intestinal contents is excreted through the wound so that the function of the diseased colon is relieved in part. Irrigations are now freely used. Schoemaker reports very favorable results with this method of treatment. The fistula can be closed off sufficiently well so that no feces escape along the drain. This is one advantage of the method.

3. *Ileostomy*: Institution of an artificial anus in the distal loop of the ileum is another surgical procedure resorted to. This operation is superior to the one just mentioned only in this respect, that the entire affected bowel is given complete rest and the passage of feces totally obviated. Here again irrigations play a large rôle in the treatment. In order to put the entire colon at rest, institution of an ileocecal anus is necessary inasmuch as one can never be positive just what part of the gut is effected. It has happened that the methods first mentioned were unsatisfactory in some cases, so eventually it became necessary to institute an artificial anus. After closure of the fistula, it is imperative to diet very carefully inasmuch as the gut has become extremely sensitive.

In a great many instances surgical treatment of such cases has brought about improvement and cure in patients who did not respond to medical treatment. The objection to operative methods is that the treatment must needs extend over a period of months or even a year or longer before the ulceration has subsided. We must also remember that the affected bowel which has not been allowed to function during this time may be shrunk or, because of adhesions of the involved areas, become stenosed so that further surgical intervention may be necessary. Regular irrigations, therefore, must be constantly carried out in cases of artificial anus in order to prevent such harmful end results.

An operative procedure which is particularly recommended by Americans is the *terminal ileostomy*. Bergen, Brown and Rankin have reported on this subject as follows: From 1921 to 1931, 82 patients with ulcerative colitis were treated in this way of which one-half died of peritonitis. Another danger associated with this method of treatment is the apparent disturbance of the water balance.

As a final refuge it is sometimes necessary to extirpate the diseased area or the entire colon. Wolvius records a case in which Michaël successfully removed the entire colon, the patient improving to such an extent that she could again carry on her work for several

years. A colon reduced to very small dimensions apparently is sufficient for proper functioning.

### VACCINE THERAPY IN THE MAYO CLINIC

Bergen succeeded in a number of patients suffering with chronic ulcerative colitis, in isolating from the intestinal ulcers a *diplo-streptococcus* which he considered the etiological factor on the basis of animal experimentation. From these diplococci, he prepared autogenous vaccines and treated his patients in this manner. From January 1, 1930, to August 1, 1931, 472 patients were treated for varying periods of time with such vaccines. In the acute stage treatment consisted of sera made of specific anti-bodies. Of this large number of patients, it appears that 352 recovered and were again able to resume their occupations.

Of the entire number: (a) 250 were symptoms free; (b) 102 showed 75% improvement; (c) 26 showed 50% improvement; (d) 45 received insufficient vaccine; (e) 49 showed no improvement.

During a period of two years, 91 patients were treated by different physicians with autogenous vaccine from the Mayo Clinic with the following results: 52 patients were symptom free; 27 were improved; 12 showed no improvement.

General as well as specific treatment was given by Bergen. In those cases, in which the ulcers could be reached with the rectoscope he applied medicated powders. In other cases, medicated enemas were administered. He also gave tincture of iodine and kaolin by mouth. The patients were allowed a general diet altho no food substances were allowed which were known to be harmful.

Bergen is of the opinion that the intestinal infection can arise from existing foci found elsewhere. For this reason he advised removal of infected teeth and diseased tonsils.

Fridkin and Gray searched for the diplococcus of Bergen in 15 cases with chronic colitis. In 12 cases this was isolated and autogenous vaccines were used. Ten of these 12 patients showed marked improvement. Three of these were seriously ill with diarrhea and intestinal bleeding when first observed. These were given small blood transfusions along with the vaccine treatment. Three patients suffered a relapse about three to four months after the termination of the vaccine therapy and bacteriological search again revealed the diplococcus of Bergen. Subsequently vaccine therapy was again successful. Kracke also feels on the basis of his investigations that the *diplo-streptococcus* of Bergen must be considered the cause of ulcerative colitis. In his opinion the treatment of the illness should consist in vaccine therapy along with general measures such as irrigations with antiseptic solutions. He gives a diet leaving very little residue. With this method of treatment he declares ileostomy infrequently necessary. Buttiaux and Sevin also acknowledge from their clinical and experimental work, the diplococcus of Bergen to be one of the causes of chronic ulcerative colitis. However, they feel that there are many other organisms instrumental in producing this affection. Among them a diplococcus isolated by themselves. They did not use vaccine therapy. Others, however, do not agree with the observers mentioned and do not ascribe much importance to Bergen's organism as a factor in this disease.

Gutierrez, Lastra and Blanco made a careful search for the diplococcus of Bergen in 16 patients with ulcer-

(prepared after operation).

---

Fig. 30.

---

Fig. 31. Pseudo-polypoid.

---

Fig. 31.

ative colitis. Isolation and culture methods were carried out by them with great care. They found a diplococcus which resembled very much that of Bergen but in experiments on rabbits it apparently was not pathogenic. They concluded that the *diplostreptococcus* was not the cause of ulcerative colitis.

Vaccine therapy was not used by them. Rafsky and Manheim also deny the etiological importance of Bergen's diplococcus in ulcerative colitis. On the basis of a large number of investigations carried out on pati-

ents as well as on normal individuals, they believe that the diplococcus is not found in all cases of ulcerative colitis and furthermore is sometimes found in the normal intestine. They did not use vaccine therapy.

The unusually favorable results following the use of auto-vaccines which Bergen and some other clinicians noted in a large percentage of their patients suffering with ulcerative colitis led us to institute that type of treatment in the patients of the Groningen Clinic.

(To be continued in May issue, Vol. II, No. 3).

## Unrecognized "Strokes" and the Gastro-Enterologist\*

By

WALTER C. ALVAREZ, M.D.  
ROCHESTER, MINNESOTA

**R**ECENTLY, while reading the memoirs of Ike Hoover, for years head usher at the White House, I was impressed with the great medical significance of what he has to say about the beginnings of President Wilson's final illness.

He tells of a few days in Paris when Wilson remained in his room with what was thought to be a slight cold. Soon he was up and back to work as usual, and to the eyes even of a physician, he might well have seemed to be the same robust, healthy man. But to the keen-eyed usher who worked beside him for fourteen hours a day, watching his contacts with the outside world, it was apparent that a great change had come. The master who had always been kindly, and friendly, and thoughtful for the comfort of those about him was now austere and distant and suspicious. He kept complaining that the house was full of French spies, and he became fussy and niggardly over little things. In the light of what happened later, it seems obvious that he had suffered the first of that series of strokes which was to influence profoundly the course of civilization.

If, as might well have happened, the President had wakened with some nausea and dizziness, and had vomited, or if he had complained of a toxic feeling, it is easy to see how a gastro-enterologist might have been called in, and how he might have blamed the state dinner of the evening before, or the shrimps, or the cheese, or the pressure of worry and overwork. And, even if Ike Hoover's observations and worries had been communicated to a neurologist, might he too not have looked up, after failing to find any sign of weakened muscles or altered reflexes, and expressed his opinion that all was well?

### *The need for asking about changes in character*

The point I wish to stress is that in many cases the physician who sees the patient after his first thrombosis is almost certain to miss the correct diagnosis, because all he hears about is an upset stomach. The changes in personality which sometimes follow are usually noticed by the family but are seldom mentioned to the physician unless he asks about them. The reason seems to be that everyone assumes that

the mental upset will disappear as soon as the indigestion is straightened out.

The home physician, who knew the man as he was before the attack of "acute indigestion," may recognize some of these changes when they appear, but he too tends to look on them as secondary to disease in abdomen or thorax. When the patient is depressed and apathetic, everyone usually agrees on one point, and this is that he should "snap out of it."

In these cases the consultant is even more likely to make mistakes than is the family physician, because he never saw the man before and cannot realize how big an injury has been wrought in the brain. Actually, the acquaintance of the medical profession with this syndrome seems to be so slight that sometimes the physicians in charge of the patient will refuse to accept the diagnosis of a mild stroke even when this is urged on them. Sometimes even the second mild "stroke," such as Wilson apparently suffered at Wichita, is looked on as a collapse due to overwork, and it is only when the big one comes, with weakness of hand or foot, or uncertainty of speech, that the true state of affairs becomes obvious.

### *A stroke can take place without any sign of shock, and without any great change in character*

The diagnosis of the first of a series of cerebral injuries is even more difficult when it takes place during sleep and the patient wakes feeling about as well as usual. To show what I mean, a very intelligent man, rose from his bed one morning to find that his unusually good memory was largely gone. His home physician refused to become concerned about this, and as so commonly happens when we medical men do not understand something, he questioned the actuality of the occurrence. A few months later, while sitting quietly at dinner, the patient suddenly felt a curious sensation in one cheek and soon found that that side of his face was anesthetic. To me the remarkable fact is that, at the time, there wasn't a trace of dizziness or headache. Careful examination by the neurologists at the Mayo Clinic left little doubt about the presence of arteriosclerotic injuries to the brain.

We see, then, that a small part of the brain can suddenly be destroyed without the production of any shock. Under the circumstances, it must be that many

of the nervous breakdowns and curious, poorly explained gastro-intestinal syndromes which we physicians see in persons past forty-five must have begun with one of these unrecognizable "strokes."

If the man whose experience I have just described had not been able to present an anesthetic cheek, he would have continued to get little sympathy from his medical advisers, and later, when perhaps he began to go to pieces mentally and physically, he might have had to part uselessly with teeth and tonsils and appendix.

#### *Some arteriosclerotics die slowly at the top*

As Janeway pointed out years ago, there are several ways in which a patient with hypertension can end up: he can die a heart death or a kidney death, or he can die by inches, "at the top." This may be well known academically, but years of consultant practice has impressed me with the fact that the opening scenes in the drama are seldom recognized for what they are. Actually, a few years ago when I wrote a description of these phenomena as I have observed them, an editor with large clinical experience refused to publish it because he thought such things were too rare to be worth talking about. But curiously, when I turned for comfort to my friend, James Kernohan, whose experience in the field of brain pathology is enormous, he remarked that he rarely showed such brains at clinico-pathologic conferences because, in the first place, they are too commonly met with to interest him any more, and in the second place, he is so often disappointed when he searches the record for the expected history of repeated short upsets with changes in personality. Too often it is apparent from the history sheet that the character of the symptoms caused the attending physicians to spend all their time hunting for the cause of the disease in thorax and abdomen.

#### SOME TYPICAL CASES

The following cases, reported briefly, will bring out some of the points I wish to make:

*Case 1.*—A woman, aged sixty-five, always active mentally and physically and proud of a host of friends, suddenly, while undressing for bed, felt a "heat wave" strike through the abdomen. Ever since then she has "felt terrible" and has been a sore problem to herself and to her daughter who looks after her.

Only careful questioning revealed the fact that for a few days after the first shock there was a slight defect in the swallowing mechanism. At the time the resultant cough was thought to be due to some infection in the throat, and it was treated in the usual way with gargles and sprays. Because the first distress was felt in the abdomen, her physicians, one after another, kept studying the digestive tract and piling up a stack of roentgenograms. As was to be expected, no one was able to find anything definite, or to help her in the slightest.

To me the outstanding feature of the case was the nervous breakdown, with its sudden onset. Two years after the first shock, when I first saw her, her complaints were the same as they were at the beginning of the illness.

*Case 2.*—Another patient, also an energetic, public-spirited, and intelligent woman who had enjoyed perfect digestion during all of her sixty years of life, awakened one morning nauseated and with the "room spinning around." The physicians who saw her were so impressed by the vomiting that they then and thereafter assumed that the trouble must be in the digestive tract. I saw her because they feared, on doubtful roentgenographic evidence, that she must be suffering with carcinoma of the colon. When

she came to this Clinic for operation, the carcinoma could not be found. Because the opening scene in the drama was so typical of a stroke, I promptly asked her, and soon obtained, a *story of a marked change in personality*, with loss of memory and of all previous interests. These troubles have persisted now for over two years, as I warned the family they would.

Incidentally one of the important things about making the proper diagnosis in these cases is that it saves the physician from giving a good prognosis and promising a cure. Such a mistake can only hurt his reputation and the cause of scientific medicine.

*Case 3.*—Another woman, aged about sixty-five, was seen by me with Dr. Wakefield. She had always had perfect digestion until one morning when, while getting breakfast, she suddenly became confused and for the next three hours kept asking her husband over and over again what had happened. Her home physicians, who apparently failed to inquire about the mode of onset of the trouble, kept looking on her problem as a purely gastro-intestinal one because all the history they obtained was to the effect that whenever she ate she was so upset that she vowed she would not eat again. The putting of any food into the stomach immediately brought on several types of distress which I believe are due to a great exaggeration of those reflexes which normally arise in the active digestive tract, and which, in some overly sensitive persons, bring flushing, excessive perspiration, or a feeling of warmth, or of sinking, or depression, or utter exhaustion.

Fortunately, in this case, the gastro-intestinal disturbances largely disappeared during the course of a year, leaving only the childishness and the loss of memory which, although a source of concern to the husband, were not mentioned by him until I asked him about them.

The next case illustrates the mistake of treating an unimportant disease:

*Case 4.*—A university president, past middle age, overworked and harassed by hostile politicians, awakened one morning with an attack of "acute indigestion." Internists in his city found a moderate hypertension, and, unfortunately, a few cysts of *Endameba histolytica* in the stools. When a strenuous course of treatment in a hospital failed to dislodge all of the amebas, the physicians wanted to attack them again, but, fortunately, the family doctor had been keeping his eyes open; he did not know much about amebas, but after years of contact with the sick he could often see the hand of death on a man's shoulder before it was visible to others. When he communicated his fears to me I backed him up, and when two months later death came to the patient after a second, larger stroke, we were glad that the tired man had been spared the annoyance of more exhausting and futile treatments.

I speak humbly of such mistakes because, as I look back over the earlier years of my practice, I can now see where sometimes I failed not only to recognize the nature of the opening scene in these dramas but I was none too sure at the *dénouement*. I know also that I must be missing the correct diagnosis in a number of these cases seen today, sometimes because I do not get all of the important history from the patient, and sometimes because I do not get enough information from the family.

The next is a case in which for a long time some doubt existed as to the diagnosis:

*Case 5.*—In January, 1920, I saw a business executive, aged fifty-three, who complained of nervousness, mental depression, spells of apprehension, and weakness of vision so that he could not read for more than a few minutes at a time. In addition, he complained of heartburn, occasional palpitation, and worst of all, of feelings of great exhaustion after eating. He expected me, as a gastro-enterologist, to cure him.

He had been strong and active until four months before I saw him, when, after overdoing at golf, he went to bed for three days with an unexplained fever. A few days before I saw him he had another similar but milder attack, again after allowing himself to become exhausted on the links. The curious thing was that after this mild indisposition, he never rallied, and for the next five and a half years, he was hardly able to answer his mail.

Many examinations failed to show anything physically wrong besides a mild hypertension and arteriosclerosis. Sometimes he complained of his stomach, and sometimes he was much concerned about his heart, but always his head did not feel right; he never could read or do much work, and at times he had dizzy spells.

After a year or so, when he came to know me better, he admitted that he had had similar sudden "nervous breakdowns" in 1902, 1909, and 1910, but then each time he was able to recover. He did not care to talk about these episodes because his father and older sister had both died after a series of apoplectic attacks.

In this case, the man looked well and kept well-groomed until the day of his death. The outstanding feature of the illness was the "nervous breakdown." Because this was ushered in by a series of short and apparently unimportant illnesses, and because it remained unchanged until he died, with what was probably a "stroke," I think the logical explanation is that the brain suffered a series of vascular injuries. Unfortunately, a necropsy was not obtained.

*One has to live close to a disease to understand it well*

I have often been impressed by the fact that the only way in which a physician can learn the fine points of a disease, and can come to understand and sympathize deeply with the sufferings of the victim and his family, is either to experience the illness himself or else to see its unfoldings in one of his relatives or close friends. Then he learns that many of the most important and troublesome symptoms, together with their repercussions on the family, do not appear on the history even when it is taken by an able clinician.

My best teachers in this field of medicine were, unfortunately, two of my closest friends, a man and his wife whom I had to watch as they died by inches in the course of several years. In the case of the husband, as so commonly happens, the first upsets were not recognized for what they were. The diagnosis began to be clear only when one of the attacks of anxiety about the heart, with a gassy stomach, was followed by violent spells of coughing due to a partial loss of the reflexes which serve to keep food out of the larynx. Later, another spell was associated with a transient weakness of the muscles of one leg, and then it became obvious that this man, long known to have hypertension, was doomed to die a cerebral death.

With each attack more of the brain was destroyed, until after two years he became so crippled mentally that he had to retire from his business. He who had been wide-awake and well-groomed, an able college president and a brilliant lecturer, a friendly man, with a host of friends, became slow and irritable and despondent, and so careless about his appearance that friends suspected him of using drugs. After two more years of suffering, with the attendant wrecking of the nerves of his wife, death came to bring him his release.

Eventually it dawned on me that some of the short illnesses that had puzzled us during the first year of this man's mental deterioration must have been due to small injuries to the brain similar to the larger ones that came later. The family and I were able then to

trace the beginnings of the disease back to a short, hitherto poorly-understood, illness that came while the patient was on a trip to the Orient. We at last understood why a man who had always been a most devoted and loving husband and a good correspondent had not written home for months at a time. When, at the time, his wife spoke to me about this, I must admit that the important medical significance of the fact was not fully grasped; in many men such behavior would not excite comment, but in this man, with his previous good record, I should have seen that this neglect was decidedly pathologic, and the first sign of a big change in personality.

Later, when the wife's troubles began, they were easier to understand, because her first thrombosis was large enough to injure the centers for speech and for the arm and leg. After recovering from this shock, she had the misfortune to live on for some six years, hoping first for recovery, and later for death. No one who has not lived close to such a patient can realize the agony of suffering that is experienced by those whose brain, the center of thought and perception, has been badly injured. I have often begged highly intelligent persons with such injuries to describe their sufferings, but it seems to be impossible for them; all they can say is that "it is awful." Perhaps it is like trying to describe an odor so that someone else can recognize it.

Even when I knew what was doubtless happening in the brain of my friend, it was hard at times to realize that a sudden attack of "acute indigestion," or of "biliousness" with vertigo, must be due to a fresh injury to the brain and not to disease in some part of the digestive tract. There is no question that some of these attacks, seen by themselves without the rest of the picture, could easily have deceived a good gastro-enterologist. That, actually, they were not due to any form of indigestion was shown by the fact, first, that before this illness the patient had always enjoyed a "cast iron stomach"; second, that the attacks came suddenly at any time of the day or night; and, finally, that at necropsy the abdomen and its contents were normal. It was the brain that was diseased, and, as was to be expected, it was easy to find the large areas of softening due to the first and the last big thromboses, with, in between, dozens of specks due to smaller injuries.

Curiously, this last patient, in spite of the aphasic and the repeated and extensive injuries to the brain, showed very little change in personality. Almost until the end she kept her keen intelligence, her wide interests, her sense of humor, and her devotion to family and friends and work.

#### SUMMARY

"Acute indigestion" in an elderly person may well be due to an unrecognized stroke. Especially when the patient goes on complaining, the physician should take note, first, of the sudden onset, and second, of changes in character with loss of memory and interests, and often of the ability to work.

Small strokes may go unrecognized because they take place during sleep or because they are not accompanied by symptoms of shock. Typical cases are described.

After a "stroke," the digestive tract may perhaps become spastic, much as an injured arm or leg is spastic, or "storms" may go down the vagus nerve, much as they do in migraine.

# Liver Function in Hepatic and Extrahepatic Diseases\*

## 1. The Results of Clinical Experience with 326 Cases

By

SAN FRANCISCO, CALIFORNIA

THE present report is the outgrowth of seven years of clinical and laboratory studies in hepatic function on patients with and without diseases of the liver, rather than the results of a comparative study of liver function tests. During this time, in an effort to obtain better insight into the patient's condition, most of the common and some of the less common liver function tests were used, the choice in individual cases depending on the promise of useful information to be obtained from any particular test under the given circumstances. The extent to which hepatic function may be influenced by extrahepatic diseases was the object of special interest and for this reason about half of the patients in this series had no direct involvement of the liver. Since among the different liver function tests only three, the Rose Bengal dye excretion test (1), the modified dextrose tolerance test (2), and the icterus index (3), were performed in a sufficient number of patients to justify definite conclusions, our report is limited to these tests.

The *Rose Bengal test* depends upon the ability of the liver to eliminate certain foreign substances from the blood-stream. The technic of this test, as used by us, was described in 1927 (1). An improvement by which the samples of plasma were compared in a spectroscope instead of a colorimeter, was introduced in 1931 (4) and utilized thereafter. The upper limit of normal for the spectroscopic method has been accepted as 55 per cent of the standard at the end of 8 minutes, and 35 per cent of the standard at the end of 16 minutes. These limits are 5 per cent lower with the colorimetric method, and this correction was added to the readings obtained prior to 1931. In instances where the specimens at 8 and 16 minutes gave inconsistent results, the latter was considered more significant. For convenience, the results of the Rose Bengal test were classified according to the degree of retention. Tests showing a retention of from 55 to 65 per cent in 8 minutes, and from 35 to 45 per cent in 16 minutes, were considered as slightly positive; those from 66 to 75 per cent and from 46 to 55 per cent respectively, as moderately positive; and those in excess of 75 and 55 per cent, as markedly positive. In classifying the results of the test, the reading at 16 minutes was again considered the more important. The Rose Bengal test was performed, often repeatedly, in 302 patients.

The *modified glucose tolerance test*, designed as a test of one of the metabolic functions of the liver, depends on the ability of this organ to maintain the blood-sugar at a certain level following the administration of insulin, dextrose, and water. At the time of the first report on this test the dividing-line between normal and abnormal function was empirically placed in the vicinity of 70 mg. per cent. In view of further experience the outcome of the test will, in this paper, be considered abnormal if the blood-sugar drops to 65 mg. per cent or lower during the test. A second criterion, applicable chiefly in borderline cases, or when the patient has an unusually low or high fasting blood-sugar, is the difference between the initial and the lowest blood-sugar during the test. In normal individuals, this difference rarely exceeds 30 mg. per cent, while in patients with impaired hepatic function it is usually higher, and may exceed 70 mg. per cent. This is merely another way of judging the ability of the liver to maintain a fairly constant blood-sugar level under the conditions of the test. Determinations of the blood-sugar were made by the method of Folin and Wu (5). Methods which exclude the non-carbohydrate reducing substances of the blood may not give comparable results. A total of 123 patients were studied by this test.

The *icterus index* was determined once or more often in 119 patients, chiefly in those with direct involvement of the liver.

Our patients have been divided into three main groups. The first comprises 106 patients with intrinsic diseases of the liver (Table I). Patients in the second group, numbering 49, had neoplasms of the liver and diseases of the malignant lymphoma type (Table V). There are considered to be invasions of the liver because without any intrinsic disease of hepatic cells, there is a destructive process involving this organ. The third group consists of 170 patients with diseases of extrahepatic nature (Table VII). Except in six instances, all our patients were ill enough to be in hospital.

#### 1. ACUTE HEPATITIS (TABLE II)

a. "*Catarrhal jaundice*." The excretory function of the liver was found to be markedly impaired in these patients during the acute stage of the disease, but to recover later. Jolliffe (6), who used the bromsulphalein test, found that normal excretion was re-established about two weeks after the height of jaundice. In our case No. 14, the Rose Bengal test became

normal while the icterus index was still 70. This is probably not an infrequent occurrence during convalescence, and indicates that quantities of bilirubin which have been stored in the tissues are being transported by the blood stream to the liver for excretion. If dye excretion remains impaired for several months after the jaundice clears up, the suspicion should be aroused that the patient had an attack of sub-acute yellow atrophy of the liver, and may be a candidate for toxic cirrhosis of the liver (Case No. 1). This is particularly likely if the attacks of jaundice recur.

The modified glucose tolerance test may continue to produce abnormally low minimum blood sugars for a time after the excretion of Rose Bengal returns to normal. From experiments on animals (7) this can probably be explained by increased utilization of sugar due mainly to hyperactivity of newly regenerated hepatic parenchyma. Possible additional factors are compensatory mechanisms in the pancreas and the muscles. When once established, they may not recede with the same rapidity with which regeneration of the liver takes place.

b. *Arsphenamine hepatitis.* Jaundice in the course of arsenical therapy of syphilis was usually accompanied by considerable impairment of hepatic function. After administration of arsphenamine was discontinued, repetition of the Rose Bengal test at intervals showed gradual improvement which, in most cases, ended in re-establishment of a normal excretory function. As was pointed out by Biskind, Epstein and Kerr (8), further administration of arsenicals should be guided by the outcome of one or more liver function tests.

c. *Toxic hepatitis.* One or more tests of hepatic function were positive in every patient of this small group. The results of successive tests on patient No. 22, with arsenical poisoning, throw interesting light on the mechanism of impairment of the excretory and metabolic functions of the liver. During the acute stage of the illness, when the patient's liver was enlarged, presumably due to necrosis and swelling of its parenchyma, there was marked impairment of the metabolic function, as measured by the modified glucose tolerance and the galactose tolerance tests. At the same time, dye excretion was normal, as shown by repeated tests, indicating that there was no interference with the biliary channels or with the permeability of hepatic cells. As parenchymatous regeneration took place it was reflected in progressive improvement of the metabolic function. In contrast to this, the excretion of the Rose Bengal dye became impaired. As

previously reported by Althausen (9), lack of connection between the new hepatic cells and the bile ducts was probably the main cause of this phenomenon, but mechanical interference with bile passages incident to shrinkage of the liver may have been a contributing factor.

## 2. CHRONIC HEPATITIS (TABLE III)

a. *Cirrhosis of the liver.* Our group of 60 patients with different types of cirrhosis of the liver were clinically characterized by hepatomegaly in 52 cases, splenomegaly in 27 cases, ascites in 30 cases, and clinical evidence of a collateral circulation in 23 cases. In this disease the Rose Bengal test is at its best, for few are the exceptions to the rule that normal results with this test practically eliminate the diagnosis of cirrhosis of the liver. Rao (10) made essentially similar observations with this test in his cases of hepatic cirrhosis.

The modified glucose tolerance test was positive with equal frequency in biliary cirrhosis. This test is, however, less reliable in atrophic cirrhosis, and is usually negative in Mallory's (11) toxic cirrhosis, which is clinically often indistinguishable from the atrophic type. The reason for this is massive regeneration of hepatic tissue in toxic cirrhosis (9) which permits normal metabolic function.

From a comparison of the icterus index with the degree of Rose Bengal retention in hepatic cirrhosis, we see a rough correlation between the two until the icterus index reaches 30 units (Table IV). Above this point, the icterus index does not indicate greater hepatic damage, as measured by the Rose Bengal test. This correlation holds only for the group as a whole, and does not mean that the dye excretion test can be replaced by estimations of serum bilirubin.

Since patients without ascites are presumably in an earlier stage of cirrhosis, it is interesting to note that the average Rose Bengal readings for 8 and 16 minutes, as well as the average icterus index, of this group were lower than those of patients with ascites.

b. *Chronic syphilis of the liver* (Table I). Hepatic function, as measured by our tests, is considerably impaired in this disease. Repeated liver function tests (up to 6 in the same patient) indicated that antiluec therapy continued over many months brought about improvement in function. This subject has been discussed in detail elsewhere (8).

A patient in this group on whom splenectomy was performed showed a temporary increase in dye retention until remaining portions of the reticuloendothel-

ial system compensated for the loss of the spleen. Similar observations on the rôle of the spleen in the removal of Rose Bengal from the blood stream were made by Dieryck (12) on splenectomized rabbits.

c. *Pyogenic and parasitic infections of the liver.* (Table I). Two patients with cholangitis gave a positive response to both tests of hepatic function. One of these patients was re-examined by the Rose Bengal test after the infection had subsided clinically, and at that time dye excretion was normal.

One patient was examined by the Rose Bengal and modified glucose tolerance tests two years after the excision of a large echinococcus cyst from the liver. At that time he had a large mass attached to the liver which was interpreted as a recurrence of his disease. Both tests were positive. Two and a half years later the mass had disappeared and the Rose Bengal test had become negative.

One patient with an amebic abscess of the liver had normal excretion of Rose Bengal.

### 3. HEPATOMEGALY

One or both hepatic function tests were performed in ten patients with hepatomegaly of undetermined origin and without other clinical evidence of hepatic disease. The results are given in Table I.

## B. NEOPLASMS OF THE LIVER

### 1. CARCINOMA

The two patients with primary neoplasms, and three out of every four patients with secondary malignancies of the liver, had positive Rose Bengal tests (Table V). The site of the primary tumor influenced the outcome of this test in the sense that metastases from near organs were more apt to cause abnormal dye retention than those from distant organs. For example, all gastric and pancreatic carcinomata in this series gave positive tests. This finding was probably due to the fact that metastases from neighboring organs have an opportunity to become more widespread by the time the primary tumor causes the patient to seek medical aid.

A comparison of the icterus index with the degree of Rose Bengal retention (Table VI) shows that the two are parallel. In addition, the bilirubinemia for the same degree of dye retention is seen to be proportionately much greater in neoplasms than in cirrhosis of the liver (compare Tables IV and VI). This suggests that, in many cases of metastatic carcinoma of the liver, it is mechanical obstruction rather than actual destruction of hepatic tissue that interferes with excretion of the dye. Such a view is supported by the

fact that the modified glucose tolerance was positive in only about half of the cases where it was done. Since this test depends on the amount of functioning hepatic parenchyma, it is more reliable than the Rose Bengal test in determining the extent to which the liver is involved.

## 2. MALIGNANT LYMPHOMAS

In diseases of the malignant lymphoma type, infiltration of the liver frequently occurs. A number of patients with such diseases were tested by our liver function tests, and several were found to have impaired function (Table V).

One patient with myeloid leukemia, marked splenomegaly, and a positive modified glucose tolerance test, had a reading of only 10 per cent of Rose Bengal at the end of 16 minutes. This is a remarkably low figure even for normal individuals, who seldom have readings of less than 20 per cent. The probable explanation is that an increase of the elements of the reticulo-endothelial system in the enlarged spleen of this patient was responsible for the removal of much Rose Bengal from the blood-stream. In this light, marked splenomegaly may mask the inability of the liver to excrete the normal amount of dye.

TABLE IV

*Correlation Between Bilirubinemia and Dye Retention In Hepatic Cirrhosis*

| Number of Patients | Icterus Index | Average Rose Bengal Reading |            |
|--------------------|---------------|-----------------------------|------------|
|                    |               | 8 minutes                   | 16 minutes |
| 12                 | 5—10          | 67                          | 41         |
| 12                 | 11—20         | 74                          | 59         |
| 8                  | 21—30         | 87                          | 77         |
| 7                  | Over 30       | 82                          | 66         |

### C. EXTRAHEPATIC DISEASES

The results of liver function tests in this class of patients were variable (Table VII). The following groups merit individual discussion:

**CHRONIC CHOLECYSTITIS.** Thirty-eight per cent of patients with this disease showed abnormal dye retention, and all but one of the positive cases were complicated by cholelithiasis. It was also noted that in almost all patients with gall-stones, the icterus index was 10 units or more. In our series, the duration of cholecystitis had little effect on the degree of impairment of the excretory function.

tolerance test, and determinations of bile-pigment in the blood and urine, were normal in his patients.

Turning from clinical to pathological evidence, Kerr and Rusk (16), and more recently Weller (17) and Beaver and Pemberton (18), described hepatic lesions in thyrotoxicosis, which could well explain functional impairment of the liver.

**2. Hypothyroidism.** Several of 8 patients with hypofunction of the thyroid gland gave positive results to both tests. In addition, two of the patients with impaired hepatic function had also enlargement of the liver and icterus indices of 11 and 20.

One patient with myxedema and a basal metabolic rate of 40 per cent minus, had a retention of Rose Bengal of 62 and 44 per cent at 8 and 16 minutes. Three months later, when the basal metabolic rate had been raised by the administration of thyroid substance, to 2 per cent plus, the Rose Bengal test gave normal readings. These results are in line with observations of Rowe (19) that 22 per cent of his patients with thyroid failure had demonstrable hepatic dysfunction.

### DISORDERS OF THE THYROID GLAND

**1. Hyperthyroidism.** About two-thirds of the patients in this group in whom one or both tests were performed exhibited functional impairment of the liver. In addition, several had an increased icterus index. We also studied another group of 16 patients with the galactose tolerance test. Thirty minutes following the ingestion of 40 gms. of galactose, 13 of these patients had blood-sugar values above 150 mg. per cent. Roe and Schwartzmann (13) feel that, after ingestion of 1 gm. of galactose per kgm. of body weight, a blood-sugar level above 150 gm. per cent constitutes definite evidence of hepatic damage. In our series, the results were made more significant by the fact that the dose of galactose was only about 0.5 gm. per kgm.

In three patients who were tested following thyroidectomy, normal dye excretion was found to be re-established.

Youmans and Warfield (14) found that one-half of the patients with thyrotoxicosis in their series of 44 cases showed impairment of hepatic function by the phenoltetrachlorphthalein test, the levulose tolerance test, the icterus index and the hemoclastic crisis. Lichtman (15) demonstrated positive cinchophen oxidation tests in 16 of 20 cases of uncomplicated thyrotoxicosis. On the other hand, the urinary galactose

**DIABETES MELLITUS.** Impaired excretion of Rose Bengal was found in some cases of this disease. One patient with marked dye retention had been in severe acidosis several times. As further evidence of hepatic insufficiency, she had, even while on a rigidly controlled regime in the hospital, frequent acetonuria and repeated hypoglycemic reactions in the presence of glycosuria.

In this connection, it is interesting that 86 per cent of the diabetic patients of Bowen, Vaughan and Koenig (21) had abnormal retention of phenoltetrachlorphthalein dye.

**ANEMIA.** A number of patients with anemias of different types showed impairment of hepatic function. In several cases of severe anemia, repeated Rose

TABLE VI

Bengal tests revealed progressive improvement of dye excretion, which paralleled the recovery of the blood.

The cause of hepatic insufficiency in anemias is probably anoxemia, as was pointed out by Rich (22) in connection with the pathogenesis of certain types of jaundice. In our group of anemias, as a whole, no correlation between the degree of anemia and the rate of elimination of Rose Bengal could be made. This is not unexpected, since in addition to anemia, anoxemia is determined by several other factors, such as the state of the circulation and the efficiency of pulmonary ventilation.

**CARDIAC FAILURE.** Over one-half of our patients with chronic passive congestion of the liver had impaired hepatic function. In several instances, the Rose Bengal excretion became normal following improvement of cardiac action. The duration of congestive failure in our patients was an important factor in determining impairment of the excretory function. This is demonstrated by the fact that the average time from the onset of the first episode of congestive cardiac failure in the group with positive Rose Bengal tests was 50 months, while in the group with a negative outcome of the test, it was only 13 months. Two patients with normal dye excretion had icterus indices of 6.5 and 7. In four patients with abnormal Rose Bengal retention, the icterus index ranged from 8 to 42. Robertson, Swalm, and Konzelman (23), Jolliffe (24), and Brooks (25) are among authors who report hepatic insufficiency in cardiac disease. In this group also, anoxemia

is the most probable explanation of functional insufficiency of the liver.

**SYPHILIS.** In most patients with this disease, but without clinical evidence of hepatic involvement both liver function tests were positive. Biskind, Epstein and Kerr (8), found that 26 out of 152 ambulatory patients had hepatic damage detected only by routine performance of the Rose Bengal test. In our series of 20 cases, the proportion of positive cases was much greater, probably because we were dealing with patients who were ill enough to be in hospital. O'Leary, Greene and Rowntree (26) published a good discussion of the significance of different liver function tests in various types of syphilis.

**NERVOUS DISEASES.** The rather frequent occurrence of positive liver function tests in disease of the nervous system is unexpected, and so far lacking an adequate explanation. Fernbach (27) pointed out that patients with such disorders are hypersensitive to insulin. This would invalidate a positive outcome of the modified glucose tolerance test. But in several of our cases, the Rose Bengal test was also positive. Furthermore, Hess and Goldstein (28), Siedhoff (29), Richet, Jacquelin and Joly (30) and Crandall (31) also found evidence of hepatic insufficiency by several function tests, in various diseases of the nervous system.

**INFECTIONS.** Several patients with a variety of acute and chronic infections not involving the liver, were found to have impaired hepatic function. This is not surprising if one considers that the liver, inci-

dent to its function of detoxication, bears the brunt of toxemias which accompany infections. A number of American and foreign authors (32-37) report similar findings in a long list of infectious diseases.

**MISCELLANEOUS GROUPS.** The modified glucose tolerance test cannot be relied upon to give information on the functional state of the liver in hyperinsulinism, or in myasthenia gravis,—in hyperinsulinism because the test depends on the maintenance of a minimum blood-sugar level which is disturbed in this condition; and in myasthenia gravis because, as previously reported (2) this disease is also accompanied by abnormalities of the metabolism of carbohydrates. The outcome of the tests in the remaining 15 cases of this group in our series is not remarkable.

It was reported previously (1 & 38) that when ascites is an outstanding physical finding, the Rose Bengal test may be very helpful in making a differential diagnosis. The test is positive in portal obstruction but usually negative in tuberculosis peritonitis. In ascites due to cardiac failure, dye retention was abnormally high in six cases out of eight.

### SUMMARY

In our patients with acute hepatitis, as a group, the Rose Bengal test was positive in 94 per cent, and the

modified glucose tolerance test in 92 per cent of cases. In chronic hepatitis, the dye excretion test was positive in 96 per cent, and the metabolic test was positive in 66 per cent of patients.

In patients with neoplasms of the liver, the Rose Bengal test was positive in 79 per cent and the modified glucose tolerance in 60 per cent of cases.

A surprisingly large proportion of patients with extrahepatic diseases showed impairment by one or both tests. This applied especially to syphilis, hyperthyroidism, congestive heart failure, cholecystitis and diseases of the hematopoietic and nervous systems.

From a comparison of the two tests in 98 patients, we see that in diseases of the liver there was agreement between them in 72 per cent of cases. In the group of patients with neoplasms of the liver, agreement between the two tests was observed in 75 per cent of cases. When both tests were used in patients with extrahepatic diseases, consistent results were obtained in 66 per cent of cases. In the last group, the least degree of correlation is to be expected because the extrahepatic factors which influence carbohydrate metabolism on one hand, and the reticulo-endothelial system on the other, are apt to be more prominent than in the two groups with anatomical involvement of the liver where the hepatic factor is dominant.

# ABSTRACTS

GEORGE E. CLOEMAN, San Francisco.

*Relapsing Fever in California. Jour. Infect. Dis. Pages 282-304, 1934, Vol. 54, No. 3.*

In two articles on the epidemiology of relapsing fever in California, the author considers the carrier condition and cross-immunity and says that there is a close relationship between certain strains of the spirochetes of relapsing fever. It appears that many workers have found the spirochetes in the brains of experimental animals long after their disappearance from the blood. However, Coleman did not find the brain infectious unless the blood was also infectious.

Bedbugs, lice, fleas, and any blood-sucking insect may convey the disease mechanically, as when biting an animal or man, but it is generally believed that transmission occurs when such insects are crushed in the clothing, or when scratching contact is made with the abraded skin. Some workers have thought that the nymphs born of ticks are the infective agents.

Some animals are naturally infected with spirochetes, among them some rodents, carnivores, and insectivores, that is, porcupines, foxes, and hedgehogs. Occasionally, too, some monkeys carry the organism. Ground squirrels seem to be immune to relapsing fever.

Strains of spirochetes of relapsing fever obtained from animals several hundred miles apart showed a close relationship. Such relationship has also been found between strains from Texas and California.

*Spontaneous Rupture of the Oesophagus in Syphilis: From Worcester State Hospital, Worcester, Mass. Amer. Jour. Med. Sci., January, 1935, p. 80.*

Mosher is cited as showing the esophagus is vulnerable to every type of lesion as in 100 consecutive organs obtained in routine autopsies he found pathological lesions in 14 specimens. Spontaneous, non-traumatic, complete rupture of the esophagus is rare. There were found no reported cases of rupture of the esophagus due to luetic peri-arteritis of the wall. In 436 consecutive autopsies in their institution 44 were on patients with syphilitic involvement of the central nervous system. Five died during "paretic seizures" and of these 2 died of hemorrhage resulting from complete non-traumatic rupture of the esophageal wall. These cases are reported. It was demonstrated that syphilis caused periarteritis in the esophagus and it is assumed that the lesions weakened the wall. Attacks of retching present in paretic seizures cause extreme intra-abdominal pressure transmitted through the diaphragm to the esophageal wall. The regurgitation of autolytic gastric contents over the lining of the diseased esophagus had an erosive effect exposing the muscular layers. The epithelial lining around the rent in both specimens was almost completely denuded. In summary the authors demonstrated that syphilitic periarteritis of the esophageal wall usually leads to vascular occlusions, scar formation and damage to the epithelial lining at those points and from the foregoing combination of events; the retching and vomiting of so-called "paretic seizures" may terminate in rupture of the esophagus.

One of their patients was a 15-year-old congenital luetic with the juvenile form of general paresis, while the other was a 58-year-old patient with acquired lues and C.N.S. involvement.

Allen A. Jones, Buffalo, N. Y.

JORDAN, SARAH M., AND KIEFER, EVERETT D.

*Complications of Peptic Ulcer: Their Prognostic Significance. Journal of the A. M. A., 103:2904, Dec. 29, 1934.*

The authors studied a group of peptic ulcer patients in whom the complications of obstruction, hemorrhage and alkalosis occurred, in order to determine what effect these complications had upon the prognosis and treatment.

There were seventy-nine cases of duodenal ulcer with obstruction. Eleven per cent of this group required surgical relief of the obstruction immediately. In the remaining cases of this group, relief was obtained by medical management. The degree of obstruction was of no significance as far as treatment was concerned since equal relief was obtained by medical management in patients with over fifty per cent retention as in those with ten per cent or under. Recurrences occurred in thirty-four per cent of the obstructed cases relieved by medical treatment. Nine per cent of this group had obstructive symptoms with the recurrence.

In forty-two patients who had gross hemorrhage, forty-three per cent had recurrent attacks in the next five years. The history of two or more gross hemorrhages is decidedly more serious. In a group of nineteen such cases, only twenty-one per cent had no recurrences in five years.

There appears to be a marked correlation between ulcer activity and intolerance to alkalis: in a group of twenty patients who showed such intolerance, recurrences occurred in seventy per cent of the cases in two years.

Single hemorrhage had the least effect on prognosis, obstruction a less favorable and multiple hemorrhage and intolerance to alkalis the most unfavorable outlook.

Francis D. Murphy, M.D., Milwaukee.

WRIGHT, D. C.

*Macrocytic Anemia and Hepatic Cirrhosis. Am. J. Med. Sci., 189:115, 1935.*

Recent literature stressing the occurrence of a pernicious-anemia like blood picture in hepatic disease is reviewed.

A summary of the blood picture in 12 cases of portal cirrhosis is presented. In these the color index ranged from 0.81 to 1.36, being greater than 1 in 9 cases.

All but one of those with red cell counts below 5,000,000 had a color index greater than unity. The average mean corpuscular volume for the entire group was 90.1, being above 90 in 7 cases. Many of these patients had a leukopenia and it is noted that this change is not limited to Banti's disease with secondary cirrhosis. Six of eight patients who were subjected to gastric analysis had no free hydrochloric acid.

In addition to this group the author presents data from 41 previously studied cases. Fourteen of this latter series had a color index of one or more and free hydrochloric acid was absent in eight of eighteen patients.

The author suggests the use of the term "pernicioid anemia" to describe this type of blood picture and feels that its presence should suggest the presence of hepatic disease. It has been reported in a wide variety of liver disturbances and so is not specific of any one condition. Wright feels that the most logical explanation for this type of anemia is that portal obstruction and gastric congestion adversely effect the formation of Castle's intrinsic factor.

## SECTION II—*Experimental Physiology*

### Decompression of the Obstructed Biliary System of the Cat\*

#### 1. Morphological Changes

By

HAROLD L. STEWART, M.D.

and

ABRAHAM CANTAROW, M.D.  
PHILADELPHIA, PENNSYLVANIA

IN view of the fact that ligation of the common bile duct has been performed in experimental animals, for various purposes, for almost 250 years, the practically complete absence of observations relative to the morphological changes which occur in the liver following restoration of bile flow becomes difficult to understand. This apparent neglect of an important phase of the process of biliary stasis is the more striking because of the relatively frequent references to serious clinical phenomena following surgical relief of common-duct obstruction. The observations of Bell (1) upon hepatic regeneration following cholecystogastrotomy in dogs with previous common-duct obstruction and those of Stewart and Lieber (2) upon the lives of human subjects following restoration of bile flow in cases of carcinoma of the pancreas, apparently represent the only previous serious attempts to investigate this problem. The literature contains occasional sporadic references to the occurrence of spontaneous reconstruction of the common duct in animals with experimentally produced biliary stasis and to the development of spontaneous bile fistulae in such animals. However, a careful search fails to reveal any data, other than those above referred to which, as a result of carefully controlled experiments, indicate the manner in which the biliary tract reacts to the sudden restoration of bile flow following total stasis of varying duration.

In previous reports, we (3, 4) have described the morphological changes in the liver and bile ducts and certain associated functional changes which occur during total bile stasis in cats. The present experiment was designed to study the manner in which these phenomena react to biliary decompression at different stages of bile stasis.

#### METHODS OF EXPERIMENTATION

The materials and methods employed were identical with those previously described in connection with the investigation of the results of common-duct ligation in cats (4), with a single exception. In order to facilitate subsequent removal of the ligature, the duct was ligated close to the duodenum, with sterile linen tape, 3 mm. wide, tied in a

double surgical knot. Autopsy upon animals that died during the period of total stasis revealed the fact that in two cases in which this knot appeared to be loose, bile could be forced from the bile ducts into the duodenum, whereas in several in which it appeared to be tight, bile could not be forced past the point of obstruction. Consequently, the data reported here are only those obtained in animals in which the ligature was firmly in place at the time of operation for its removal. This was performed in different animals at varying intervals following ligation of the common duct. At the time of the secondary operation, sections of liver and kidney were removed in most instances for the purpose of comparing the lesions of stasis with those of decompression in individual cases. The ligature was removed by carefully releasing the knot by means of two pairs of mosquito forceps and only those animals are included in this report in which the contents of the ducts promptly filled the segment distal to the point of ligation. The animals were subsequently killed and autopsied at varying intervals following release of obstruction. All instances were excluded in which the duct system was not perfectly patent and in which bile could not be readily expressed through the ampulla of Vater. By the observance of these precautions we feel reasonably certain, although we cannot be absolutely sure, that the duration of total stasis and that of decompression have been accurately timed.

At the time of operation in many cases, the wall of the common duct was found to be necrotic and eroded at the site of the ligature; in several the duct was ruptured in attempting to remove the ligature; in a few instances spontaneous rupture of the duct had occurred above the point of ligation. These animals were excluded from the present report as were those in which any evidence of infection was noted other than small, localized stitch infections. The following data therefore represent observations upon 19 cats with total bile stasis of 1 to 16 days duration followed by decompression of 1 hour to 7 days duration. In 12 instances cholecystectomy was performed at the time of ligation of the common duct.

#### EXPERIMENTAL OBSERVATIONS

##### GROSS CHANGES

Following removal of the obstructing ligature, the liver diminished in size and became rather flabby with wrinkling of the capsule. The consistency varied, de-

Fig. 1.

pending upon the duration of stasis, the degree of fibrosis and the extent of regressive changes. In cases in which complete stasis had existed for 1-8 days, the previously distended extrahepatic ducts collapsed promptly as illustrated by their condition in Cat 119, 2 hours following relief of stasis of 6 days' duration. The increased fibrosis associated with more prolonged stasis (10-15 days) appeared to interfere with complete collapse of the extrahepatic ducts, which were observed to be markedly dilated even after 4 days of decompression.

Bile was present in the intestine and could be expressed through the ampulla of Vater in all but 2 cases (Cats 63 and 86), in which there was apparently acute suppression of bile formation. In the former, the extrahepatic ducts contained a thick white, mucoid material and the intrahepatic ducts were empty; in the latter the ducts contained a small quantity of thin pale fluid. No constant alteration was noted in the color or consistency of the bile in the other animals.

#### PIGMENTATION

Pigmentation of the liver during total bile stasis in cats is extremely variable in distribution and intensity, bearing no constant relation either to the duration of stasis or to the degree of bilirubinemia (3, 4). A similar variability was observed following decompression although, in general, the degree of pigmentation tended to diminish rather rapidly following restoration of bile flow. However, a few distinct exceptions to this general rule were noted. In cat 86, in which there appeared to be practically complete suppression of bile secretion, pigmentation was more marked one day after decompression than after 7 days of stasis. An increase was also present in Cat 87, 7 days after decompression of an obstruction of 4 days' duration. Similar changes were noted in cats 119, 152 and 82. In some instances, the pigment granules appeared to stand out more distinctly than in the static liver cells.

In a few cases, particularly Cat 119, a change appeared to occur in the relative distribution of pigment in the hepatic and Kupffer cells. Only 2 hours after release of obstruction, the Kupffer cells, which had previously contained large quantities of pigment, had

Fig. 1. Sporadic necrosis and intralobular architectural distortion, with loosening of the hepatic cells from their reticular attachments following decompression. Photo. micro. mag. circ. 80 x.

become markedly swollen and vacuolated and distinctly less pigmented. This decrease in pigmentation appeared to be coincidental with the increase in vacuolization and the vacuoles appeared to occupy areas previously occupied by pigment granules. A simultaneous increase in pigment was noted in the hepatic cells and canaliculi.

In two instances (Cats 131, 128) in which the subcapsular zone showed marked regressive changes, but not hyaline necrosis, this area was much more deeply pigmented than is ordinarily the case in the liver of stasis. In Cat 132, in which pigmentation was generally marked, scattered throughout the liver were large cells, apparently hepatic cells, which were vacuolated and deeply pigmented. In many places they were collected in groups, the largest comprising about 35 cells, the line of demarcation from the surrounding parenchyma being usually sharp and consisting of a canaliculus. These lesions which occurred indiscriminately in all parts of the lobule were regarded as probably localized areas of necrosis, the pigment granules standing out against the necrotic and vacuolated cytoplasmic background. Sections of this liver, stained with Nile blue sulphate, contained a large amount of lipid material, confined almost exclusively to Kupffer cells except for the above-mentioned necrotic areas which were also heavily laden with lipid droplets, standing out in sharp contrast to the surrounding fat-free parenchyma.

In one animal (Cat 152) small nodular, pigmented lesions, situated at the periphery of several of the lobules, were observed in various stages of regression (Fig. 2). The degree of pigmentation of the monocytic cells of this lesion diminished progressively and there was a simultaneous increase in the degree of vacuolization of these cells. Coincident with these changes, there was a progressive increase in lymphocytic and chiefly plasma cell infiltration.

#### ARCHITECTURAL CHANGES IN PARENCHYMA

Disruption of the intralobular architectural pattern constituted one of the most prominent features of the decompressed liver. In its advanced form it presents a rather characteristic picture (Fig. 1). The cells lie singly or in short cords of 6-15 cells, in varying stages of degeneration, necrosis and cytoplasmic disintegration, with fraying and tearing of the reticulum. As a result of these changes the canaliculi frequently communicate directly with the perivascular tissue spaces which are usually edematous and may contain red blood cells, extruded from ruptured sinusoids. The architectural distortion is usually most marked in the inner third of the lobules and about the larger bile ducts but, in some cases, may be confined to the subcapsular region or may occur in localized areas throughout the parenchyma.

This condition of parenchymal disorganization was present in some degree in every case, following decompression of 1½ hours' to 7 days' duration. The changes were minimal in animals in which biliary stasis had existed for only 24 hours, increased more or less progressively to reach a maximum following 6-10 days of stasis, and were less marked and ex-

Fig. 2.

tremely inconstant in cases following obstruction of 11-15 days' duration. In the latter, the architectural distortion was generally confined to or most marked in the region of the larger bile ducts.

#### REGRESSIVE CHANGES

Although somewhat variable, the degree of sporadic necrosis tended to be more marked following decompression than during stasis. This was particularly true in cases with decompression of relatively brief duration and, to a lesser degree, in those in which the pre-existing period of obstruction had been limited to 1-3 days. The extent of sporadic necrosis in some instances is illustrated by cases 131, 119 and 120, in which only 20-50 per cent of the hepatic cell nuclei could be identified in stained sections. This lesion appeared to be less marked following decompression of longer duration (viz. Cat 82), due probably to restoration of the parenchyma by active regeneration of hepatic cells.

Focal mid-zonal areas of necrosis were noted in 5 animals, 119, 82, 64, 72 and 116, with stasis of 6, 8, 11, 11 and 12 days' duration, and decompression of 2 hours, 3 days, 1 day, 4 days and 1 day respectively. In each instance these lesions were in an advanced state of regeneration. In Cat 116 these lesions showed a marked plasma cell infiltration and in the others they were almost completely effaced by regenerating hepatic cells. In Cat 82 the cells at the periphery of the area of necrosis were sending short cord-like processes into the lesion, which showed mitotic figures and other evidences of regeneration.

In the liver of stasis, the tissue immediately beneath the capsule consists of pale-staining, swollen, vacuolated or finely-reticulated hepatic cells with sharply outlined borders and indistinct oval nuclei which frequently appear as basophilic smudges; these degenerative changes tend to remain stationary unless complete necrosis supervenes (3). No change was noted following decompression in some cases. In others, as in Cats 86, 121 and 82, the hepatic cells in the subcapsular zone showed distinct improvement (1-3 days decompression). The chromatin material in the nucleus stained more sharply, the cells decreased in size and both nucleus and cytoplasm assumed a more normal appearance. Many of the cells were smaller than previously and the cytoplasm became smoother, less reticulated and more deeply staining. These changes were accompanied by a coincident dilation of the sinusoids in this area. In Cats 72 (stasis 11 days, decompression 4 days), and 64 (stasis 11 days, decompression 1 day) the subcapsular zone was still finely reticulated and many cells were necrotic but individual cells here and there had assumed a normal appearance. In Cat 128 (stasis 15 days, decompression 2 days) this area was badly damaged although the regressive changes in the remainder of the parenchyma were minimal. Cats 143, 147 and 63 showed a distinct increase in the extent and degree of degeneration, necrosis and vacuolization following decompression of 1-3 days' duration. An area of subcapsular hyaline necrosis was present in Cat 116 following decompression of 24 hours duration; although this lesion

was not observed in the biopsy specimen (12 days stasis) it cannot be regarded as necessarily absent at that time because of the possible variable distribution of such lesions in the liver of total stasis.

A variable degree of hyaline necrosis was present at autopsy about the larger bile ducts in 5 cases (Cats 119, 121, 77, 72 and 116) but in no instance was it possible to determine whether this lesion had increased in extent or degree following decompression because of the impossibility of obtaining biopsy specimens from these areas of the liver during stasis.

#### BILIARY PASSAGES AND CONNECTIVE TISSUE

A conspicuous point of difference between the liver of stasis and that of decompression lay in certain prominent changes in the epithelial cells of the small proliferated and medium-sized bile ducts and in the infiltrating lymphocytes, monocytes, plasma cells and polymorphonuclear leukocytes. In several instances the cytoplasm of these cells was completely vacuolated, the portal radicles in paraffin sections bearing a close resemblance to xanthomatous nodules (Fig. 3). The nature of the substance responsible for this appearance was not determined but it did not stain with fat or glycogen stains. The monocytes and polymorphonuclear leukocytes appeared to be involved in the process of vacuolization earlier and more extensively than the plasma cells and lymphocytes, which seemed to resist this change. In some instances the resulting enlargement of the epithelial cells and infiltrating cells was so marked as to produce complete occlusion of the lumens of the smaller and medium-sized ducts. The epithelial lining cells of the larger ducts exhibited this change to a less extent and, in Cat 86, a similar process was observed in the cells of a localized inflammatory reaction on the peritoneal surface of the liver. In other cases the vacuolated epithelial cells were observed in process of phagocytosis by the invading macrophages, which were occasionally accumulated in masses within the lumens of the ducts.

In the early phase of this process the bile duct epithelial cells appeared pale and swollen and stained irregularly; the nuclei were large and clear and the chromatin material appeared to be diminished. Some

Portal area showing extensive swelling and vacuolization of the lining epithelial cells of a medium-sized bile duct which are infiltrated with inflammatory cells; "a" indicates lumen, "b" basement membrane. The process involves many of the infiltrating cells and is also present, although less marked, in the larger duct (c) in the lower portion of the field. Note distortion of structural arrangement on the left. Photomicro. mag. 200 x.

Fig. 3.

of these cells were undergoing necrosis and cytoplasmic disintegration but these changes were relatively inconstant and inconspicuous. The development of this phenomenon seemed to be related more directly to the duration of stasis than to that of decompression, for it was not observed in any case in which common duct obstruction had been maintained for less than 4 days. It was noted in variable degree of intensity as early as 1-3 hours following decompression in animals with 6-8 days stasis (Cats 119, 120), and was most marked in Cat 86 (stasis 7 days, decompression 1 day). In Cat 87 (stasis 4 days, decompression 7 days) vacuolization was still present in the smaller but very slight in the medium-sized ducts and appeared to persist longest in the basal portion of the cells.

During stasis the mucosa of the larger ducts undergoes progressive proliferation which becomes very marked, particularly after the tenth day when it presents a papillary and adenomatous appearance, with multiplying cylindrical epithelial cells several layers deep supported by hyperemic fibrous tissue with a few inflammatory cells. The smaller ducts show mitotic figures and budding within the first 24 hours and grow out from the portal radicles in the form of cords of cells supported by connective tissue with no demonstrable lumen. They insinuate themselves between the hepatic cells of adjacent lobules, the majority of which, after the 21st day, are surrounded by a collar of these proliferating elements. As early as 1½ hours after release of obstruction in an animal (Cat 123) with 10 days stasis, the adenomatous formations in the mucosa of the larger ducts showed marked epithelial cell necrosis, the disintegrating cytoplasm being continuous with the granular albuminous contents of the lumen. Some of the bile-duct cells were being phagocytosed by macrophages and polymorphonuclear leukocytes and the epithelial lining showed marked denudation, the cells being cast off into the lumen. This regressive process became progressively more marked with prolongation of the state of decompression (Cat 72, stasis 11 days, decompression 4 days). The connective tissue about the larger ducts became markedly edematous and more fibrillar and less compact than during complete stasis. The newly proliferated smaller ducts also underwent regression and, with the accompanying connective tissue, were displaced and crowded by regenerating hepatic cells, became atrophied and eventually disappeared (Figs. 4 and 5). Isolated cords of bile duct cells could be seen lying in small groups, without a lumen, and long cords were frequently interrupted by actively regenerating hepatic cells. These changes were marked within the first 3 days following relief of stasis. In some cases, lumenization of certain cords occurred coincidentally with compression, atrophy and disappearance of others and eventually, as in Cat 87 (stasis 4 days, decompression 7 days), the proliferated ducts regressed to the point where every one which remained was lumenized.

In several cases (especially Cat 86), as in stasis, destruction of newly proliferated ducts was effected by the accumulation in their lumens of a pink hyaline secretion; this produced compression and necrosis of the lining epithelial cells which appeared to liberate a stringy, basophilic substance which was ultimately removed by the action of phagocytic cells. With the restoration of bile flow, canalicular casts, which are numerous during stasis, gradually disappear and in favorable cases the canaliculi ultimately reassume their normal appearance. Recovery was practically complete in one animal 7 days after release of obstruction (Cat 87). Marked architectural distortion was naturally associated with a corresponding degree of canalicular disruption but marked dilatation of the canaliculi persisted in some cases of protracted stasis with little or no disturbance of the architectural pattern.

#### BLOOD VESSELS AND KUPFFER CELLS

The sinusoids, which during stasis had been compressed to a variable degree by proliferating and distended bile ducts, frequently became dilated and hyperemic during decompression. This change was observed in the subcapsular area as well as in the parenchyma generally and was noted as early as 2 hours (Cat 119) after relief of obstruction of 6 days duration. This state of hyperemia and dilatation rendered the outlines of the sinusoids and the liver cell cords more distinct than during stasis. In some instances the reticular walls of the sinusoids were torn, resulting at times in small hemorrhages. The Kupffer cells were very prominent, swollen and vacuolated, and frequently were actively phagocytosing red blood cells. Their nuclei were often large and partially karyolyzed. Many Kupffer cells, swollen and filled with debris, were observed within the lumen of the central and sublobular veins and sinusoids, the latter being at times almost completely occluded by these elements. Changes in the pigmentation of the Kupffer cells have been described previously.

In several instances there was marked edema of the perisinusoidal and other perivascular tissue spaces and occasionally previously compressed arteries were assuming a more normal appearance. In one case (Cat

82) there was a large area of infarction associated with thrombosis of large branches of the hepatic artery and portal and hepatic veins. In Cat 63, thrombosis of some of the smaller portal radicles was associated with apparently acute suppression of bile secretion.

#### REGENERATION

Although regression of bile ducts is a very prominent feature of decompression, mitotic figures occasionally were observed in the bile-duct epithelium, indicating an attempt at active regeneration. Of particular interest, however, were the regenerative changes in the hepatic parenchyma, which constituted one of the outstanding features of the liver of decompression. Although present elsewhere, these changes were most pronounced in the region of the smaller portal radicles where the hepatic cells, during the period of stasis, had gradually become atrophied and compressed by the distended and proliferating bile ducts. In this situation the hepatic cells became swollen, more numerous and more prominent, with a clear, finely reticulated cytoplasm and hyperchromatic nuclei. Binucleation, multiple nuclei and active mitosis were frequently observed. These newly formed cells insinuated themselves among the proliferated ducts, compressing them and crowding them aside (Figs. 4 and 5); in some instances small islands of bile-duct cells had been apparently snared off and were surrounded by the regenerating hepatic cells. In the majority of cases the bile-duct epithelial cells and the young hepatic cells could be readily identified on the basis of the characteristic appearance of the latter, described above, and the small compressed, pyknotic, sharply staining condition of the former. In some instances, however, certain cells in this situation could not be positively identified.

During stasis, the regressive changes in the subcapsular zone either remain stationary or eventuate in a narrow band of hyaline necrosis. The necrotic material in this area is cleared away by phagocytic cells and the still viable cells in the adjoining parenchyma, without showing binucleation or mitosis to any appreciable extent, appear to move in a sheet toward the capsule, against which the phagocytes and necrotic material, which is being rapidly evacuated, are being compressed (4). In spite of careful search in more than 70 animals, mitotic figures and other evidences of regeneration were not observed in the subcapsular zone proper during stasis. Following decompression, particularly in cases with 4-10 days stasis as described previously, improvement in the condition of the cells in this area was evidenced by diminution in vacuolization and by accentuation of cellular outline and of the chromatin material in the nucleus. This improvement progressed until the majority of the cells of the subcapsular zone had reassumed an essentially normal appearance (Cat 87, stasis 4 days, decompression 7 days). In sharp contrast to the findings during stasis, numerous mitotic figures were observed in this area following decompression (Fig. 6), as were other evidences of active regeneration, such as binucleation, multiple nuclei and nuclear enlargement and hyperchromasia. Complete restoration of the subcapsular region as well as the remainder of the parenchyma appeared to be a relatively slow process, for active mitosis was noted as late as the seventh day following relief of obstruction (Cat 87).

The frequency with which mitotic figures were observed in the hepatic cells was very striking, mitosis being in general much more active during decompression than during stasis; in some cases as many as 3 mitotic figures were noted per oil immersion field (Fig. 7). In animals in which stasis had been maintained for 10-15 days, decompression was accompanied by very little evidence of active regeneration despite the fact that nuclei of normal appearance were exceedingly numerous. Whatever evidence of regeneration was present was practically limited to the region of the larger bile ducts. In Cat 86, with apparently complete suppression of bile secretion, regeneration of hepatic cells was very slight, no mitotic figures were observed and the cells about the proliferating bile ducts remained compressed.

#### DISCUSSION

##### PIGMENTATION

Following surgical decompression of an obstructed biliary system in man, hepatic pigmentation diminishes progressively and rather rapidly in patients who survive the immediate effects of the operation (2). In the cat, however, the distribution and intensity of pigmentation, which are extremely variable during total stasis, are equally variable during decompression. The changes in the relative distribution of pigment in the Kupffer and hepatic cells noted in Cat 119, 2 hours after relief of obstruction, are of extreme interest. The simultaneous decrease in Kupffer cell pigmentation and increase in hepatic cell pigmentation suggest a rapid movement of bile pigment in this direction following restoration of bile flow. The increase in the degree of pigmentation of the subcapsular zone during decompression in certain cases and the apparent increase in pigment in scattered areas of necrosis in others are interesting but the significance of these changes is conjecturable.

The exact nature of the small nodular pigmented lesions noted in Cat 152 could not be determined. Their situation at the periphery of the lobule is identical with that occupied by biliary necroses in man. The component cells of these lesions could not be positively identified when observed during total stasis in a previously studied group of animals; they were regarded either as hepatic cells, bile duct epithelial cells or macrophages and were believed to have resulted possibly from interference with the passage of bilirubin from the canaliculi into the duct system due to the interposition of fibrous tissue. During decompression it became apparent, as a result of diminution in the intensity of pigmentation of these lesions, that at least some of the constituent cells are hepatic cells. This suggests that the remaining, still unidentifiable cells may also be hepatic cells, but no definite statement can be made in this connection on the basis of the available material. As the morphological characteristics of these lesions became more readily demonstrable, an alveolar arrangement was suggested, but the degree of architectural distortion, although not marked, was sufficient to preclude the possibility of more positively identifying their structural characteristics. The fact that bile ducts could never be demonstrated in these lesions, coupled with the fact that proliferated ducts in various stages of regression were extremely numerous elsewhere throughout the parenchyma, suggests two possibilities: (1) that bile ducts may actually constitute the structural basis of

Figs. 4 and 5. Illustrating different stages in regression of small proliferated bile ducts. Note encroachment by newly regenerated hepatic cells and the characteristic large, clear and pale appearance of the latter. Photomicro. mag. 200 x.

these nodules, being obscured by the relatively intense pigmentation; (2) that these pigmented lesions develop at the site of a bile duct which has undergone complete destruction as a result of changes associated with total bile stasis. The significance of the plasma cell infiltration and of the vacuolization of the constituent cells of the lesion, which progressed simultaneously with the decrease in pigmentation, cannot be stated.

#### ARCHITECTURAL CHANGES

Disruption of the intralobular architectural pattern following decompression in the cat is quite similar in appearance and distribution to that noted in human beings by Stewart and Lieber (2). The pathogenesis of this lesion, as discussed by these authors, probably is dependent purely upon mechanical factors resulting from the sudden fall in the elevated intraductal and probably intravascular pressures consequent upon release of obstruction of the common bile duct. The fact that distortion of architecture was slight in animals following stasis of only 24 hours' duration may be attributable, on this basis, to a relatively slight increase in these pressures during the early stage of stasis. The inconstancy of these changes in animals in which biliary obstruction had existed for 11-15 days may be due to the fact that the increase in fibrous tissue which develops during this period tends to prevent the marked loosening and shaking-up of hepatic cells which is a striking feature of decompression in cases with stasis of briefer duration.

#### REGRESSIVE CHANGES

The increase in the degree of sporadic necrosis noted in the majority of cases in the early stage of decompression following obstruction of relatively brief duration (1-3 days) appeared to represent merely an accentuation of those lesions already present during stasis. Although the process of restoration of the parenchyma in these areas of sporadic necrosis was not followed by serial biopsy examinations in individual cases, the fact that these lesions were less marked in animals at longer intervals after release of common-duct obstruction suggests that their disappear-

ance was due to parenchymal restoration by actively regenerating hepatic cells (*viz.* Cat. 82).

It is possible that the areas of sporadic necrosis in the cat are essentially analogous to the regressive lesions which are a prominent feature of the liver of decompression in human subjects. However, in man these lesions are most marked about the central veins, extend peripherally into the lobules and bear a close anatomical and quantitative relation to the associated distortion of intralobular architecture. In the cat, this latter relationship is not maintained and the regressive changes are distributed sporadically throughout the lobule, bearing no particular relation to the central veins or portal radicles. Moreover, this necrotic process never attained the proportions in cats which it does in man and, even when marked, was not accompanied by evidences of suppression of bile secretion.

#### BILE PASSAGES AND CONNECTIVE TISSUE

The process of vacuolization of the small and medium-sized bile ducts, which was an outstanding feature during decompression in cats, was never observed following surgical relief of bile stasis in humans. Likewise it was never present in the liver of stasis of humans or cats. Except for the fact that the substance responsible for the vacuolated appearance of these cells did not give the characteristic staining reaction of fat, lipoids or glycogen, its chemical nature was not determined. The possibility that this change may be due to edema cannot be disregarded, although this seems unlikely in view of the absence of comparable grades of edema throughout the hepatic parenchyma and the presence of similar changes in the infiltrating macrophages and, occasionally, in inflammatory cells in certain cases. Moreover, the absence of precipitated granular material within the vacuoles would indicate that if this phenomenon is due to edema, the fluid must have an unusual chemical composition in that it contains an extremely small amount of protein, if any. The fact that the cells involved frequently are phagocytosed by macrophages suggests that the process is to some extent regressive in nature; however, some of the affected cells of the bile-duct

epithelium undoubtedly recover completely and the various stages in the disappearance of the vacuoles could be followed in some instances, the process persisting longest in the basal portion of the cells.

With the removal of the apparent stimulus to proliferation coincident with the restoration of bile flow, restoration of the normal structure of the larger bile ducts was effected by necrosis, desquamation and phagocytosis of their extensively proliferated lining epithelial cells. The occasional disappearance of medium-sized ducts by the accumulation of hyaline material and phagocytic cells within their lumens was noted during decompression as during stasis. Changes in the newly-proliferated smaller bile ducts constituted a striking feature of the decompression. The majority of these underwent regression and were displaced, compressed and the continuity of their cords interrupted by actively regenerating hepatic cells so that eventually they became atrophied and disappeared. The connective tissue accompanying these

relation to groups of necrotic hepatic cells, mitotic figures, as well as other signs of active regeneration, were most numerous in the peripheral portions of the lobules in relation to the smaller portal radicles (Fig. 6). The changes which occur in the smaller bile ducts and adjacent hepatic cells during decompression are in sharp contrast to their condition during the period of obstruction. During total stasis, these ducts and their supporting stroma undergo proliferation and regeneration, whereas the dominant change in the adjacent parenchyma is regressive in nature. During decompression these conditions are reversed, the proliferated elements in the smaller portal radicles undergoing rapid involution and regression coincidently with and probably as a result of active regeneration of the surrounding hepatic cells.

Mitotic figures in bile duct epithelium can be readily distinguished from those in hepatic cells on the basis of their respective characteristics. Mitosis was occasionally noted in cells of proliferated bile ducts

Fig. 6. Mitotic figure in hepatic cell (a) in subcapsular zone. Note group of bile duct epithelial cells immediately below and margin of liver on the left border of the illustration. Photomicro. mag. circ. 700 x.

Fig. 7. Three mitotic figures in single oil-immersion field (a, b and c), in mid-zone of lobules, "c" being slightly out of focus. Photomicro. mag. circ. 800 x.

proliferated bile ducts was ultimately compressed into thin strands of compact collagen fibrils interspersed with a few pyknotic, spindle-shaped nuclei. In some cases, lumenization of certain cords occurred coincidently with regression of others, until eventually every small bile duct which remained was lumenized.

#### REGENERATION

In the cat, as in man, there is marked evidence of active regeneration of hepatic cells following release of obstruction of the common bile duct. In the latter, however, we were unable to find mitotic figures at any time during either total stasis or decompression, whereas, in the cat, active mitosis was noted under both conditions, being more marked during decompression. There is no obvious explanation for the absence of mitotic figures in the subcapsular zone during total stasis and their appearance in this situation following restoration of bile flow. Although distributed generally throughout the hepatic parenchyma, frequently in

which were undergoing regression but in no instance was it possible to demonstrate a transition from these cells to hepatic cells. The cells in these regions, referred to above, which could not be positively identified as either bile-duct epithelial cells or hepatic cells, did not appear to represent a transition stage of this nature.

A point of particular interest is the fact that the activity of regeneration appeared to diminish after the tenth day of stasis both in animals in which obstruction was maintained for a longer period and in those in which decompression was effected after this time. In view of the activity of the regenerative process during the earlier period of stasis, it is probable that the majority of the hepatic cells which are viable at this time were generated following ligation of the common bile duct. The diminished activity of regeneration in such animals, even during decompression, may be dependent upon a diminished reactivity

to stimuli which would ordinarily produce either regressive or regenerative changes in hepatic cells with stasis of briefer duration.

### SUMMARY

1. Diminution in the intensity and distribution of pigmentation is extremely variable during decompression of the obstructed biliary system of the cat. In some cases a decrease in Kupffer cell pigmentation occurred simultaneously with an increase in hepatic cell pigmentation, suggesting a rapid movement of bile pigment in this direction. Peculiar pigmented nodular lesions were noted, the exact nature of which could not be determined.

2. Increase in the extent of regressive changes and a rather characteristic disruption of the intralobular architectural pattern were prominent features of the liver of decompression.

3. A rather constant finding was that of a peculiar process of vacuolization involving the lining epithelial cells of the smaller and medium-sized bile ducts and the associated infiltrating cells. The nature of the sub-

stance responsible for this vacuolization was not determined but it was apparently neither fat nor glycogen.

4. The proliferated bile ducts tended to regress to the point of complete disappearance. This occurred simultaneously with and was perhaps largely dependent upon active regeneration of adjacent hepatic cells which eventuated in lobular expansion and more or less complete restoration of the parenchyma in these situations. These regenerative changes, in which active mitosis played a prominent part, also occurred sporadically throughout the remainder of the lobule, frequently in relation to single and aggregated necrotic hepatic cells. In the restoration of the hepatic parenchyma, the process of active regeneration was supplemented by the recovery of degenerated but still viable cells.

STEWART G. BAXTER, M.D., Ph.D.  
MONTREAL, CANADA

IT was established some time ago by Babkin (1904) and Sawitsch (1909) that the three principal enzymes of the pancreatic juice—trypsin, lipase and amylase—are secreted by the pancreatic gland of the dog in parallel concentrations. The greater the digestive power of any one of these enzymes in the juice, the greater was that of the other two. To demonstrate these relations between the enzymes it was necessary to activate the protrypsin of the inactive pancreatic juice with the enterokinase of the intestinal juice, and the prolipase with bile. The amylase of the pancreatic juice is secreted in an active form and does not require any activator. Food containing fat stimulated a flow of pancreatic juice rich in all three enzymes, whereas carbohydrate and especially protein produced a secretion with a lower digestive power. Babkin and Tichomirow (1909) then found that the higher the proteolytic, and hence the lipolytic and amylolytic, power of canine pancreatic juice, the higher was its nitrogen concentration. In comparing the nitrogen concentrations of different samples of the juice, they found that the relations between them corresponded very closely with the relations between the squares of the millimeters of the digested protein of the corresponding juices in the Mett's tubes. Therefore, instead of estimating the enzymatic power in different samples of the pancreatic juice, they suggested that the digestive power of the juice might be more accurately determined by ascertainment of the nitrogen concentration by Kjeldahl's method.

From study of a case of pancreatic fistula in a human subject, Wohlgemuth (1907) likewise found that trypsin, lipase and amylase were secreted by the pancreatic gland in parallel concentrations. In Table I are quoted figures for the concentration of trypsin,

TABLE I

| Food         | Volume c.c. | Trypsin | Amylase | Lipase |
|--------------|-------------|---------|---------|--------|
| Carbohydrate | 75.0        | 5.3     | 4.8     | 225.0  |
| Protein      | 66.0        | 10.89   | 6.25    | 529.0  |
| Fat          | 35.0        | 14.97   | 10.89   | 954.8  |

amylase and lipase in the pancreatic juice of this patient after meals rich in carbohydrate, protein and fat. The "concentration" of enzymes is calculated by Wohlgemuth from the square of the digested column of coagulated protein or starch, or the square of the number of cubic centimeters of alkaline solution required for the neutralization of fatty acids.

The pancreatic juice possessed the greatest proteolytic, lipolytic and amylolytic power when secreted on food rich in fat. The enzymatic activity of the juice was less when its flow was stimulated by food containing much protein or carbohydrate.

Recently Balo and Lovas (1933) studied the relative amounts of trypsin, amylase and lipase (glycerol extracts prepared by the method of Wilstatter and Waldschmidt-Leitz) in the pancreatic gland of persons who had died of various diseases (70 cases). A parallelism

\*Department of Physiology, McGill University.  
Submitted January 25, 1935.

was generally found between the concentrations of the three enzymes. In sepsis, however, the tryptic activity of the pancreatic extract was greatly decreased, while the amylolytic and lipolytic activities remained normal. In two cases of fat necrosis of the pancreas the content of lipase was increased. It must not be forgotten that the authors were working not with the pancreatic juice but with extracts of the glandular tissue.

These investigations establish the fact that in the pancreatic gland of a carnivorous dog or an omnivorous man the three principal enzymes are always secreted in parallel concentrations.

No reference could be found in the available literature concerning the secretion of pancreatic enzymes in parallel concentrations by the herbivorous animals (*cf.* Mangold, 1929). During investigation of the pancreatic secretion in the rabbit (Baxter, 1931, a and b) this problem presented itself and became the subject of a special study, which is reported here.

### METHODS

Rabbits were anaesthetized with urethane, 1 gr. per. kg. of 20 per cent solution being injected intravenously. In some experiments the animals during brief ether anaesthesia were decerebrated or decapitated. The pancreatic duct was cannulated and the pancreatic juice was collected in half-hourly or hourly samples. Since the pancreatic gland of the rabbit secretes spontaneously, in many experiments in order to obtain more uniform results the pylorus and the bile duct were ligated.

For determination of the proteolytic enzyme Mellanby's (1912) method of coagulation of calcified milk was used. This method is based on the assumption that all proteolytic ferments coagulate milk, provided the calcium content of the milk be adequate. The protrypsin was activated by the enterokinase solution prepared by grinding 30 gr. of intestinal mucosa to which 100 c.c. of water were added. Each cubic centimeter of pancreatic juice was activated by incubation with 2 c.c. of enterokinase solution on a water bath (40° C.) for one hour. 0.1 c.c. of the activated juice was added to 2 c.c. of milk solution and incubated at 40°

C. The first appearance of flocculent particles was taken as the end-point. The time required for the coagulation of the milk by a given sample of pancreatic juice was converted into an arbitrary value in units; these were in inverse relationship to the time of coagulation.

The amylolytic power of the juice was determined by the method of Waksman (1920). This enzyme was not activated in this series of determinations.

For the determination of the lipolytic activity Mellanby's (1925) method was adopted. One series of determinations was performed on inactivated juice, another on a juice activated by bile.

### RESULTS

Figure 1 represents an experiment in which 1.5 mg. of pilocarpin hydrochloride were twice injected intravenously. This drug augmented the volume of the spontaneous secretion and very distinctly increased the enzymatic power of the juice. This parasympathomimetic effect of pilocarpin may be explained by the fact previously established (Baxter, 1931 *b*) that the vagus is a secretory nerve of the pancreas. Faradic stimulation of the vagus increases the pancreatic secretion in the rabbit and raises the digestive power of the juice.

Whereas the concentrations of trypsin and lipase run closely parallel with each other both after the first and after the second injection of pilocarpin, the rise of the amylolytic power of the juice after the first administration of the drug is relatively smaller than after the second. It would be more correct, however, to attribute this fact not to actual dissociation of the discharge of enzymes from the glandular cells but rather to the imperfection of our methods of enzyme determination, to the destruction of one enzyme by another, or perhaps to the different inorganic composition of the pancreatic juice secreted under various conditions. However, without further investigation, necessitating the most accurate methods of enzyme determination, it is impossible to ascertain the extent of this parallelism between the different pancreatic ferments.

The second injection of 1.5 mg. of pilocarpin increased the volume of the secretion practically to the same degree as did the first, but it failed to produce the same rise in the enzymatic power of the juice as occurred after the first injection. This probably was due to exhaustion of the stores of zymogen granules in the cells of the pancreatic gland.

Figure 2 shows another experiment in which the flow of the pancreatic juice and its digestive power were likewise increased by two injections of pilocarpin of 1.5 mg. each. Only trypsin and lipase were determined in this experiment. The latter was activated by bile. The results of the lipase determination are expressed in cubic centimeters of 0.01 N NaOH as a direct measure of the lipoclastic power of the juice. The relations between the trypsin and the lipase during the course of this experiment remained in general the same as in the previous experiment when the lipase was not activated. Every rise and fall of the trypsin was followed by a rise and fall of the lipase. But the absolute lipolytic power of the juice owing to its activation by bile was much higher in this experiment than in the preceding. The highest figure for the activated lipase was 24 c.c. of 0.01 N NaOH solution, whereas the highest lipoclastic power of the inactivated juice was only 12 c.c. of the same solution.

Fig. 2.

### DISCUSSION

The structure of the pancreatic gland is very uniform. There is only one kind of secretory cell, containing the zymogen granules. Therefore, it is very probable that one and the same acinous cell elaborates all three of the principal pancreatic enzymes. Nothing, however, is known about the intimate mechanism involved in the formation and secretion by the acinous cells of the pancreas of these or indeed any of the half dozen pancreatic enzymes. A special experimental and clinical study of the enzymatic activity of that part of the pancreatic gland which is in the service of the external secretion of the organ, is highly desirable. However, even the imperfect knowledge which we now possess of the interrelations between different enzymes of the pancreatic juice may have an important practical value.

One of the methods employed in determining the functional activity of the acinous tissue of the pancreatic gland in patients is the estimation of the enzymatic power of the aspirated duodenal contents. There is hardly any diagnostic procedure more uncertain than this, because the duodenal contents may include up to fifteen enzymes and activators, each of which may interfere with the action of the others. The task of the clinician might be simplified somewhat if the parallel concentration of the three principal enzymes of the pancreatic juice were taken into consideration. This being admitted, it would be sufficient for the estimation of the functional activity of the pancreas to determine the power of only one of the many enzymes of the pancreatic juice. Katsch and von Friedrich (1922) on the other hand advise determination of all three enzymes in the duodenal contents aspirated after injection of a small amount of ether into the duodenum of the patient. According to these authors ether produces a secretion of pancreatic juice in which the three enzymes do not occur in parallel concentrations. But they themselves consider this an unphysiological method of producing pancreatic and other duodenal secretions—with which statement probably hardly anybody will disagree.

Let us discuss briefly the relative diagnostic value of determining each of the three chief pancreatic enzymes in the duodenal contents.

Although the *succus entericus* contains an *amylase*, the action of the latter is very weak. Therefore it does not play any essential part in the intestinal digestion of carbohydrates (cf. Babkin, 1928, p. 768, and Oppenheimer, 1925, vol. 1, p. 725), and can hardly interfere with the determination of the pancreatic *amylase*. But the possibility that saliva, which possesses a strong *amylase*, may be present in the duodenum, cannot be excluded. Certain data indicate (cf. Oppenheimer, 1925, vol. 1, p. 424) that salivary *amylase* is not all destroyed by the acid of the gastric juice, and some of it may be reactivated in the duodenum, so that one *amylase* may be taken for the other. Further difficulties arise because, according to Kuhn (1925) and Reichel (1932), both the salivary and the pancreatic *amylase* belong to one and the same group of  $\alpha$ -*amylase*. Purr (1934) believes that the salivary *amylase* belongs to the  $\alpha$  type, whereas the pancreatic *amylase* is a mixture of the  $\alpha$  and  $\beta$  types. But the difference in this respect between the two preparations investigated by Purr might be due to the fact that in one case he used a true secretion, i.e. human saliva, while for the study of the pancreatic *amylase* he employed acetone-ether-dried pig's pancreas. Therefore the presence of tissue enzymes in this latter preparation is highly probable. In this connection it is worth while to mention that *beta*-*amylase* may be extracted from rat's liver and from many plants. All this makes the differential determination of the salivary and pancreatic *amylases* in the duodenal contents very difficult, and hence the estimation of the functional capacity of the pancreatic gland uncertain.

It is true that the *pancreatic lipase* plays a predominant role in the intestinal digestion of fat, because the lipase secreted by the intestinal mucosa is far less active. However, the presence of the latter in the duodenal contents cannot be ignored.

According to Waldschmidt-Leitz and Schöffner (1926) the *pancreatic erepsin* and the *intestinal erepsin* are identical (cf. Oppenheimer, 1926, vol. 2, pp. 875 ff.). On the other hand Leberton and Mocoroca (1931) deny the presence of erepsin in the pancreatic juice. They showed that of the five enzymes found by Wilstatter, Waldschmidt-Leitz and their school in the extracts of the pancreatic gland, namely prokinase, proteinase, carboxypolypeptidase, and two ereptic enzymes, i.e. aminopolypeptidase and dipeptidase, only the first three enzymes pass into the *pancreatic juice*. The ereptic enzymes are endocellular and are present only in the extracts.

We come now to the discussion of trypsin determination. Since the time when Shepovainikov (1899), working in Pavlov's laboratory, discovered *enterokinase*, it has been known that the intestinal juice does not digest coagulated protein. It dissolves fibrin, but this requires from 14 to 16 hours, whereas the activated pancreatic juice does it in a few minutes. From native proteins casein and gelatin are also split by the intestinal juice, which action is ascribed by Waldschmidt-Leitz and Schöffner (1926) to the *intestinal trypsin*. This effect, however, is very weak. Therefore, it seems that the determination of trypsin in the duodenal contents is the most reliable method for the

estimation of the external secretory function of the pancreatic gland. This is evident from the fact that pancreatic trypsin will attack coagulated protein in an alkaline medium, which no other enzyme of the gastro-intestinal tract could do.

The old Mett's method (digestion of coagulated egg-white), somewhat modified, still may be recommended as a suitable clinical method for determining the tryptic activity of the pancreatic juice. Although it cannot be considered so accurate as other more elaborate methods of protease determination, its advantage lies in its simplicity and reasonable dependability. The application of Mett's method in clinical

practice was recently reconsidered by Patterson and Adler (1932) and found by them to be quite suitable.

#### SUMMARY

(1) The parallel concentration of trypsin, amylase and lipase in the pancreatic juice of the rabbit is demonstrated. These data are in conformity with those obtained from analogous studies by previous investigators of human and canine pancreatic juice.

(2) The possible application of these data to the practical problem of functional diagnosis of the external secretion of the pancreatic gland is discussed.

My thanks are due to Dr. B. P. Babkin for his interest in this problem, and for his helpful advice and criticism during the progress of the work.

## ABSTRACTS

C. G. BURN, New Haven, Conn.

*Postmortem Bacteriology. Jour. Infect. Dis. Pages 388-403.*

This very important subject is discussed in two very interesting articles. The bodies studied were subjected to a temperature of 10° C. (50° F.) within a short time after death and were kept there until the necropsy was performed. Opportunity was not at hand for study of bacterial invasion during the first hour after death or at the time of death. It was found that a large group of pathogenic and nonpathogenic bacteria failed to invade the tissues after death, even though ample opportunity was given for such invasion. Organs and body fluids, however, disclosed a high incidence of bacterial growth at necropsy. Lungs, kidneys, liver, spleen and blood from the heart show frequency of growth in the order named. *B. coli*, staphylococci, *Clostridium welchii*, and nonhemolytic streptococci are the more frequently isolated strains of bacteria. Other types isolated are usually associated with disease states within the body. "No significant differences can be demonstrated in either the frequency or the kind of bacteria isolated from organs, post mortem between the first and forty-eighth hour after death." The quantity of organisms, their location within the body, and the time between death and necropsy may be important factors influencing postmortem invasion.

J. Arnold Bargen, Rochester, Minn.

F. D'HERELLE AND T. L. RAKIETEN, New Haven, Conn.

*Mutations as Governing Bacterial Characters and Serologic Reactions. Jour. Infect. Dis. Pages 313-338.*

The number of bacterial mutants arising from a single strain under action of phage is indefinite. *Salmonella enteritidis* was used in this study. All mutants differ in some precise characteristics. The transformations are not stages in the life cycle of the organism. Bacteria can be made to carry phage, thus creating symbiosis between the separable entities, a bacterium and a phage. In such a symbiosis, each of the components adapts itself to the action of the other; the phage as well as the bacterium undergoes modifications in its characters.

The study of bacterial mutants leads to important immunologic data. The pathogenicity of bacteria is governed by mutations under the action of phage. Some mutants from an original pathogenic bacterium are completely avirulent, while others are fully as virulent as the original strain. There may be all manner of intermediaries, including those provoking a chronic disease.

In a diseased organism not only does the host undergo modifications, leading to production of antibodies, but at the same time the invading bacteria, through the action of phage, undergo modifications, leading to what appears to be increased sensitivity to the action of complement.

J. Arnold Bargen, Rochester, Minn.

MANN, FRANK.

*Hepatic Function in Relation to Hepatic Pathology; Experimental Observations. Ann. of Int. Med., VIII, 432, Oct., 1934.*

An imposing array of hepatic function tests is all but consigned to discard in an account of experimental work done on the liver.

If regret be felt for the threatened fatality to diagnostic procedures, some consolation may be winnowed from the wreck in the knowledge that physical restoration of removed or injured liver tissue went on at an extent not shared by most other organs and exceeded by none. It affords strange reading to be told that the restorative activity of the liver "makes it difficult to produce, experimentally, a decrease in the functioning hepatic tissue to such an extent that the hope would be justified that the physiological activity had been reduced to an amount that could be measured."

Partial removal of the liver, even as much as 70 per cent, was followed by rapid and complete restoration of liver tissue. Several weeks' administration of carbon tetrachloride were required to produce a condition analogous to cirrhosis in the human liver. The mechanical obstruction of bile flow injures only one function of the liver unless maintained for months. It appears that only a combination of the various methods for damaging liver tissue or impairing function will make such damage or impairment permanent. Concerning the functional attributes of the liver emphasis is placed on (a) the normal liver has a capacity much in excess of the normal needs of the body; (b) the functional capacity of the liver depends on a number of factors and changes with great rapidity; (c) impairment of one function may not impair any other function of the liver; there seems to be even a dissociation of the functions of the liver; (d) singularly, despite this dissociation of its own functions, there is an association or correlation of liver functions with those of other organs which makes difficult delineation of hepatic factors; (e) normal hepatic functions can be carried on by a very small bit of normal liver tissue.

In studying liver function bile ranks as the oldest. Cholesterol, bile pigments and bile acids are the most important of these; not enough of the source or significance of cholesterol is known to warrant its determination helpful as a function test. Of bile pigments bilirubin has been thought to be the best index to liver injury, but its significance in estimating function is modified by (a) its origin from hemoglobin. (b) Much of the total bilirubin found

in the body is of extra-hepatic origin. (c) All of the body bilirubin could be excreted by a very small amount of liver tissue. (d) Tests for bilirubin estimate the amount retained in the blood, but do not furnish adequate data for estimation of hepatic damage. Bile salts are found in traces only in health and are not definitely detectable in the blood. The administration of large amounts result in little or no increase in the excretions or the blood. Bile salts are not formed when the liver is removed. The liver both forms and destroys bile salts. Concentrations of bile salts in the blood and urine are significant of liver injury, but it is doubted if their estimation can be used as a hepatic function, chiefly because the liver both makes and destroys bile salts.

Certain dyes are largely disseminated by the liver. The rate the liver removes such a dye is an index to that function alone and is not a physiological measure of other liver functions. Some pathological changes were found to bear no relationship to dye excretion; this is especially true of scirrhus changes.

Considering the liver in relation to carbohydrate metabolism and the tolerance tests based on this function, attention is called to the fact that the fate of dextrose depends on so many extra-hepatic factors that changes in glucose tolerance cannot be considered indicative of impaired hepatic function. The glycogen content of a normal liver may vary as much as from 1 to 20 per cent.

Since muscles can make glycogen from levulose, it follows that levulose might be utilized where there was little liver function left. Therefore, levulose tolerance tests to measure liver injury are not thought worth while.

Galactose is a sugar largely used by the liver, but there exists a wide difference in the rate of its use in normal animals; its use as a sugar-function test would seem useless.

A study of the nitrogen partition in blood and urine in animals and the effect of liver injury on these phases of metabolism was thought to indicate that hepatic injury cannot be quantitated by changes in nitrogenous excretion.

The author concludes that no quantitative relationship could be found between the amount of functioning liver tissue and the capacity of such tissue to maintain any of the known functions of the liver. That destruction of liver tissue short of death an animal produces little or no changes in those physiological processes which are abolished by total removal of the liver.

Virgil E. Simpson, Louisville.

## SECTION III—Nutrition

### MILK

By

HORACE W. SOPER, M.D.\*  
ST. LOUIS, MISSOURI

A REVIEW of the recent literature concerning milk as a food for human beings reveals many interesting observations. Man appears to be the only mammal which habitually consumes milk after the period of lactation has ceased.

Crumbine and Tobey (1) in their excellent monograph on milk state that as a result of their researches it was used as a food 4000 years B.C. The Aryans of Central Asia were the first herdsmen, and honey and milk was a prized drink. Goats' milk and mares' milk were consumed by the ancient Greeks. The ancient Egyptians depicted the heavens as a cow with a full udder.

Most authorities on nutrition, particularly McCollum (2), consider milk a food for which there is no adequate substitute. He advises that one quart of this "protective food" a day should be consumed. He points out that the inhabitants of the wet regions in southern Asia subsist on a diet of rice, soy beans, sweet potatoes and many other vegetables. Bamboo sprouts and other leafy vegetables are eaten in large quantities. They have no herds and do not consume milk. He states that these people are better developed physically, have more capacity for work and endurance, that they escape the skeletal defects in childhood, and have the finest teeth of any race in the world. In the dryer regions of the world, the people consume large amounts of sour milk. Metchinkoff, forty years ago, became interested in the large number of centenarians among the Bulgarian peasants. He attributed their longevity to the life-long habit of drinking sour milk, fermented by the *lacto-bacillus Bulgaricus*.

Timothy Leary (3) in his work on athero-sclerosis states that man is the only animal who ingests eggs and milk throughout its lifetime. Man is the only animal, as far as is known, who dies in early life from coronary sclerosis and which acquires athero-sclerosis almost universally in advanced life. He was impressed with the high content of lipoids in atheromatous aortae. He conducted a series of experiments—feeding rabbits cholesterol. He also studied cases of human coronary sclerosis. Cholesterol is the only sterol found in animal bodies. It forms the framework of all animal cells. It combines with fatty acids to form esters. In our dietary, eggs, milk, and pork fats are the main sources of supply. He concludes that the lesions of human athero-sclerosis can be reproduced in the rabbit by feeding cholesterol. The inheritance of

a poor cholesterol metabolism appears to be associated with the tendency to early death from coronary sclerosis. Leary points out that the custom formerly used of feeding diabetics diets excessively rich in fats, resulted in a great increase of athero-sclerosis in the subjects.

Joslin (4) suspects high cholesterol blood content as the etiological factor in cataract and arteriosclerosis. He emphasizes the importance of keeping the fat in normal limits in diabetics, at least under 230 mg. of cholesterol per 100 c.c. of blood.

Rabinowitch (5) calls attention to the relationship between the carotin and cholesterol content in the blood of diabetics and arteriosclerosis.

Milk is an important constituent of the alkaline-ash diet as emphasized by Sansum and his co-workers.

Dental caries, root infections, and pyorrhea form too large a subject to attempt elucidation here. Bunting concludes his study of the subject as follows: "To this end it is highly desirable that group studies be made in which the allied sciences of chemistry, nutrition, bacteriology and dentistry may be correlated in a truly scientific attack on this difficult and important problem in human welfare." Can milk be implicated as an etiologic factor? Ernst A. Hooton (7), Professor of Anthropology at Harvard University, in a broad survey of "The Teeth of Apes and Men," a recent article in the "Scientific Monthly," concludes that "foci of infection in teeth undermine the entire bodily health of the species and that degenerative tendencies in evolution have manifested themselves in modern man to such an extent that our jaws are too small for the teeth which they are supposed to accommodate." "I firmly believe that the health of humanity is at stake and unless steps are taken to discover preventatives of tooth infection and correctives of dental deformities, the course of human evolution will lead downward to extinction." Professor Hooton points out that primitive man was singularly free from tooth infection with the single exception of the Rhodesian man—equipped with the longest face, the largest palate, and the worst teeth of antiquity; that examination of the skulls of savage races reveals that they did not suffer from dental caries and apical abscesses. The teeth are usually found to be worn down by attrition. It is notable that such people were not consumers of goat's or cow's milk. Professor Hooton is greatly impressed with the fact that nine out of ten school children in the United States have decayed teeth.

\*From the Soper-Mills Clinic.  
Submitted January 9, 1935.

McCollum (2) emphasizes the necessity of the presence of vitamins "D" and "C" and adequate amounts of phosphorus and calcium in the dietary for the development of good teeth.

The bacterial flora of the intestine of breast fed infants shows a preponderance of the bacilli known as *lacto-acidophilus*. The intestine of the adult abounds in proteolytic bacteria.

Bunting (8), Professor of Oral Pathology in the University of Michigan, came to the following conclusions after five years research work. "Dental caries is dependent on the infestation of the mouth by specific types of bacteria capable of producing acids by the fermentation of residual carbohydrate food materials and capable of living in their own products. *Lactobacillus Acidophilus* is the organism always found in dental caries. It is never found in the mouths of persons free from dental caries. It is also found in the intestinal tract of carious persons." Bunting believes that the character of the foods eaten by civilized people is a great factor in the production of dental caries. Primitive peoples living on simple foods are free from caries until they come in contact with civilization.

Kopeloff, Blackman and McGinn (9) examined the feces of 208 adult inmates of an institution and found *Bacillus Acidophilus* in 62% of them. No dietary restrictions were imposed. They state that constipation was not a factor.

Roettger (10) states that he and his associates have demonstrated the occurrence of high acid-producing bacteria in dental caries, which proved to be streptococci.

Rosenow discovered the presence of streptococci in apical abscesses and demonstrated their relationship to gastric and duodenal ulcer, appendix and gall bladder infections.

An important report (11) on the milk supply of London was recently made. It appears that the milk is gathered in the country and transported to London in large glass-lined tanks, each holding 3000 gallons. These tanks contain milk from different herds. The first examination of ten road and rail tanks showed all contained living virulent tubercle bacilli. The latest figures for tank milk show that out of forty-one samples, thirty-four or 83% contained tubercle bacilli. After pasteurization and examination of two hundred and eighty-two samples purchased over the counter, nine or 3.2% contained tubercle bacilli.

In the cities of Edinburg, Glasgow, Aberdeen and Dundee (12), specimens of pasteurized milk as retailed gave a figure of over 5% of samples that contained tubercle bacilli. In England, 45% of tuberculosis of the cervical glands, 47% of lupus, 30% of tuberculosis of the meninges, and 18% of that of bones and joints have been found to be due to the bovine bacillus. In Scotland the corresponding figures are 73, 53, 12 and 42.

The work of Saunders (13), *et. al.*, in "Infection in Gastric and Duodenal Ulcer" is of extreme importance. Their conclusions are as follows: "The organism studied by us is found in milk from cows suffering with mastitis, and is not identical with any other type of streptococcus tested. It will stand the heat of pasteurization, it does not live in bile media of the lowest dilutions, and is not affected by a high acidity. It is the only factor which can explain the epidemic-like

occurrence of ulcer in children from one to six months of age as reported by Helmholtz (14). An identical organism has been isolated from thirty resected ulcers of the stomach and duodenum, and has been proved identical with three others isolated from cows milk, and is not identical with any other streptococcus tested. Following surgical duodenal drainage in dogs, 14 typical ulcers were found in five of the group of ten fed cultures of the organism, and only 2 erosions in two of the control group of nine not fed the organisms."

"Place and Sutton (15) have reported an epidemic of arthritic erythema or Haverhill fever which was traced to the use of raw milk. They have isolated an organism (*Haverhillia multiformis*) found in the blood and fluid of involved joints of patients suffering from the disease."

"G. M. Fyfe (16) reports a Milk-Borne Sonn  dysentery epidemic affecting 150 persons."

Rosenow (17) reports an institutional outbreak of poliomyelitis in a midwestern college apparently due to a streptococcus in raw milk. The epidemic ceased to spread after discontinuance of the use of unpasteurized milk and cream.

Rosenow, Rosendaal, and Thorsness (18) have reported the results of their investigation in the Minnesota epidemic of poliomyelitis. They found a streptococcus isolated from raw milk at the time of the epidemic that was identical with that isolated in cases of poliomyelitis in human beings and monkeys, in its thermal death point, in its morphology and cultural characteristics, in its immunologic properties, and in its cataphoretic velocity. They also found the poliomyelitis streptococcus in several samples of pasteurized milk.

Much work has been done on the subject of pathogenic bacteria in milk by Ayres and Johnson (19) who found that pasteurized milk soured due to the development of lactic acid bacteria which had survived pasteurization or due to reinfection. They also state that the relative proportion of groups of peptonizing lactic acid and alkali or inert bacteria in pasteurized milk is about the same as in raw milk. In later articles they point out that the "majority" thermal death point is quite different from the "absolute" thermal death point of bacteria (20) and (21). Prucha (22) found that pasteurization reduced the bacteria count in milk in general about 99% but under certain conditions, the milk became heavily contaminated with bacteria that had resisted pasteurization temperature. The way in which the milk was handled had much to do with the effectiveness of pasteurization. He found that no spore-forming organism was completely destroyed at 62.2° C. (144° F.) (23). Bacteria which may survive pasteurization are classified as follows:

1. Heat resistant non-spore-forming bacteria
2. Thermophilic bacteria
3. Streptococci
4. Non-thermophilic spore-forming bacteria.

The cow is essentially an unclean animal. Efforts to sterilize the udder are unavailing. The skin cracks and becomes eczematous and the scabs fall into the milk. Mastitis is a frequent development. Despite all strenuous efforts and precautions, the best milk delivered from the dairies continues to show the presence of pathogenic bacteria.

## THE EVAPORATED CANNED MILK

Marriott (24) in 1929 pointed out the great advantages in feeding this milk to infants and young children. He states "that a large or tough curd could not be formed in the stomach or intestine from evaporated milk. There are good reasons for supposing that a fine curd from milk used for infant feeding is desirable. The protein is more completely digested when small curds are formed in the stomach, bacteria are not enmeshed and removed from the influence of the bacterial acid gastric juice." Furthermore, he fed 752 young infants evaporated milk and concluded that it is the full equivalent of pasteurized or boiled whole cow's milk. He had splendid results in feeding the evaporated milk to premature infants. Following Marriott's leadership, pediatricians all over the country are practically unanimous in supporting this opinion. The literature on the subject is voluminous. I mention Brennemann (25), Lowenburg (26), Koch and Samuels (27), Tobey (28), Kerley (29), Cutler (30), Jeans and Stearns (31), and many others. Todhunter (32), Kramer, Latzke and Shaw (33), demonstrated that evaporated milk gave a higher calcium balance than did fresh milk and pasturized milk.

In the year 1929, Crumbine and Tobey (1) asserted that evaporated milk was "The most nearly perfect food." "Because of its many sanitary and economic advantages, this is the milk supply of the future, though it is improbable that evaporated milk will supersede whole milk supplies in our large cities in the next few years." "Sometime ago, the late Dr. Hermann M. Biggs, State Commissioner of Health of New York, prophesied that eventually all milk would be in the concentrated form. His forecast has not yet come true, but as the public comes to appreciate the safety, uniformity, stability, digestibility, nutritional quality, convenience, and inexpensiveness of the concentrated milks, this prophecy of Dr. Biggs' may eventually be more nearly accomplished."

Davidson, Biguria and Guild (34) conclude their study of the use of evaporated milk as follows: "With regard to the influence on gastric acidity and motility, our experiments seem to indicate that evaporated milk, diluted and undiluted, may be used as well as milk and milk and cream mixtures, in the treatment of conditions that require a bland or semi-bland diet." Ross (35) treated a series of cases of peptic ulcer and concludes "that the use of evaporated milk in ulcer diets is a further advance because it is easily digested, contains no lactic acid bacilli, and it is sterile." Todhunter (32) reports that young rats on a vitamin G free diet were fed diluted evaporated milk, pasteurized milk, and whole cooked egg, as sources of vitamin G. Of diluted evaporated milk 10.1 c.c. per week, of pas-

teurized milk 9.3 c.c. per week, and of egg 5.2 grams per week were found to give "unit growth" of 24 grams over a period of eight weeks. The vitamin G values found for market milk and for evaporated milk diluted according to the directions on the container are, therefore, substantially alike.

About four years ago, I became convinced that raw as well as pasteurized milk contained pathogenic bacteria and advised boiling milk and cream. In time, I employed the evaporated milks particularly in cases of gastric and duodenal ulcer, ulcerative colitis, catarrhal colitis, etc. The results were so satisfactory that I prescribed the canned evaporated milks exclusively in my diet-lists for such conditions. Ulcers healed more quickly and recurrences were less frequent. Ulcerative colitis patients responded especially well and relapses which formerly were so common are now rarely encountered. Many cases of catarrhal colitis are quickly corrected by this simple change in dietary habits. A complete report of my clinical experience with the evaporated milks will be made later.

Recently I submitted to the Gradwohl Laboratory, 13 specimens of milk, representing the different St. Louis dairies. These were cultured according to the United States Health Standards.

5 of the specimens showed the presence of streptococcus viridans

4 showed staphylococcus albus

2 showed acidophilus

1 showed encapsulated streptococci which failed to grow in cultures

1 showed almost a pure culture of pneumococci-like organisms.

The tremendous importance of the problems involved is obvious, particularly so in view of the fact that all our municipalities are engaged in strenuous but futile attempts to secure a pure milk supply.

*The following conclusions appear to be justified:*

1. Research into the habits of the people of ancient as well as modern civilizations reveals that they were consumers of milk and all suffered from dental caries.

2. Raw milk is unfit for human consumption.

3. Pasteurized milk as it reaches the consumer, usually contains pathogenic bacteria and is not to be relied upon as a safe food.

4. The canned evaporated milk is sterile, more easily digested, keeps in the tin indefinitely without refrigeration, and contains all the elements of nutrition desirable in milk. Furthermore, its general use by the public would mean a tremendous economic gain.

6. Should the experimental work of Bunting and that of Timothy Leary receive general confirmation, it would indicate a complete readjustment of our alimentary habits.

## ABSTRACTS

RIVERS, ANDREW B.; STEVENS, J. ARNOLD, AND KIRKLIN, B. R.

*Diverticula of the Stomach. S. G., and O., 60:106-113, Jan., 1935.*

In a short but rather complete paper the authors discuss the disease and present reports of 14 proved cases (ten removed at operation and four obtained at autopsy). There were no characteristic symptoms of the disease and even roentgenologic findings were not particularly definite. The size varied from 1 to 7.5 centimeters. Surgical treatment of diverticula in the upper portion of the stomach is indicated when the presence of the diverticulum is proved and no other cause for the epigastric distress can be found. When present in the lower 2/3 of the stomach operative measures, preferably resection of the diverticula, are always advisable because of the possibility of an associated malignancy. An excellent bibliography is included in the paper.

J. Duffy Hancock, Louisville.

BAUER, WALTER.

*What Should a Patient With Arthritis Eat? Journal of the A. M. A., 104:1, Jan. 5, 1935.*

The author presents a useful classification of arthritis. He divides all arthritis into two main groups, one group the origin of which is known and a second group of unknown or uncertain origin.

In the group of arthritis of known origin, with the exception of gout, no special diet is indicated.

In the group of arthritis of uncertain or unknown etiology, the author distinguishes two groups which he states must be considered separately because they are distinctly different disease processes.

In the degenerative or hypertrophic arthritis, the etiology is the "wear and tear" incident to increased age and repeated trauma. Inflammatory processes, endocrine dysfunction and metabolic disturbances do not cause this type of arthritis. Other than a reduction type of diet in the obese to relieve a weight-bearing joint, no special diet is necessary.

Proliferative or rheumatoid arthritis is of unknown etiology. Infection is an important etiologic agent in the general opinion.

The omission of acid fruits and vegetables is one of diet used in treatment. These acid fruits are weak acids. They

are the chief source of Vitamin C. There appears to be no reason for removing these fruits from the diet.

There is no evidence to show that mixed diets—protein, fat, and carbohydrate taken together—are in any way incompatible.

There is no apparent truth in the theory of an "acid system" in rheumatoid arthritis. A well balanced diet maintains the acid-base balance of the body.

If food hypersensitivity exists it must be definitely determined and the offending food removed from the diet. If such hypersensitivity exists in rheumatoid arthritis, it must be rare.

A low protein diet in rheumatoid arthritis is not justified and may be harmful.

Reduced caloric intake has not been shown to be of value.

There has been no definite evidence to show that a low carbohydrate diet is of any special value in the treatment of this type of arthritis.

Because of the inadequacies of the average diet, the author feels that a high vitamin, high caloric diet with calcium, phosphorus and iron should be used in these cases.

LEONA M. BAYER, M.D., AND H. GRAY, M.D.

*Obesity Treatment by Diet, Thyroid and Dinitrophenol, Result of 106 Outpatients. Am. J. Med. Sc., Vol. 189, No. 1, p. 86, Jan., 1935.*

The authors summarize their results on the treatment of obesity under dietetic treatment supplemented with the administration of thyroid and dinitrophenol.

They advise a course of dietetic treatment before exhibiting dinitrophenol. They describe the ill effects of three cases who were treated with dinitrophenol.

Reports of the toxicity of this drug have persuaded many physicians to suspend its use altogether. There has been a number of fatal cases reported in the literature, and the drug unquestionably is being used by the laity as it is sold indiscriminately by the drug trade. The sale of dinitrophenol should be restricted to physicians' prescriptions, and in many instances physicians would do well to omit its exhibition in the treatment of obesity.

H. W. Soper, St. Louis, Mo.

## SECTION IV—*Roentgenology*

### Dysphagia—Roentgenologically Considered\*

By

L. S. OTELL, M.D.

and

FRED O. COE, M.D.

WASHINGTON, DISTRICT OF COLUMBIA

THE physician is consulted frequently by patients whose chief complaint is "difficulty in swallowing." A carefully taken history and a thorough physical examination may reveal the cause, may give some diagnostic clue or may be entirely misleading. In most instances the basic pathologic lesion is a matter of conjecture unless a more direct method of approach is employed.

The roentgen method not only gives valuable information concerning lesions both within and outside of the esophagus but involves no unpleasant manipulative procedures and is entirely without danger. The esophagoscope in the hands of the master is often an important adjunct in confirming the roentgen diagnosis and in many instances may give more accurate information concerning certain intraesophageal lesions. On the other hand it renders little assistance in the large group of extraesophageal conditions which may seriously interfere with swallowing. Concerning the bougie as a diagnostic implement in the esophagus we shall merely quote a passage from Barclay (1) in which he says: "Of the bougie it is difficult to write with patience. If other and less dangerous methods are available it is an act of crude barbarity to pass such an instrument for diagnostic purposes into a tube the walls of which may be the seat of simple or malignant ulceration or may be eroded by an aneurysm. The bougie is a most useful surgical instrument . . . . . but for diagnosis there is no other such savage relic in the whole of medicine or surgery."

The roentgenologist in his capacity as a consultant is intrusted with the oftentimes difficult problem of disclosing as far as possible the actual pathological condition which interferes with the swallowing act. He should therefore not only be thoroughly acquainted with the roentgen patterns of the various lesions which may be encountered but should be able to correlate them with the clinical manifestations. The history, the presence of other related symptoms, the laboratory findings and the physical examination are helpful in making a diagnosis and in the many doubtful cases which he encounters esophagoscopy should be advised.

There are many causes of dysphagia. The large group of diseases of the pharynx and larynx, *i.e.*,

acute tonsilitis, lingual tonsils, laryngeal and pharyngeal ulcerations are not of particular interest to the roentgenologist, inasmuch as these conditions are usually demonstrable by direct vision. The discussion in this paper will center around the large number of intraesophageal and extraesophageal lesions which for the sake of convenience have been divided into three groups depending upon their frequency of occurrence.

#### Group 1. (most common)

- a. Foreign bodies.
- b. Achalasia of the cardia (cardiospasm).
- c. New growths.
- d. Esophageal orifice hernia.

#### Group 2. (less common)

- a. Compression stenosis.
- b. Diverticula and pharyngeal pouches.
- c. Congenital atresia.
- d. Paralysis of the esophagus.
- e. Cicatricial stenosis (traumatic).
- f. Esophageal varices.
- g. Dysphagia of anemic women.

#### Group 3. (rare)

- a. Benign tumor.
- b. Peptic ulcer of the esophagus.
- c. Thoracic stomach.
- d. Syphilis.
- e. Tuberculosis.
- f. Esophagitis.
- g. Mycotic stenosis.
- h. Dysphagia associated with gastric lesions.
- i. Herpes, urticaria, angioneurotic edema, serum sickness.
- j. Spasm of the esophagus.
- k. Atony of the esophagus.
- l. Globus hystericus and hysteria.

#### FOREIGN BODIES

The diagnosis and ultimate behaviour of foreign bodies in the food passage is to a large extent a roentgenological problem. The roentgenologist usually comes in contact with these patients early and observes them either until the foreign body is removed or passes spontaneously.

The *history and symptoms* are important in the diagnosis. There is usually a subjective feeling that something is stuck in the throat. This may be fol-

ful in showing the relationship between the esophagus and trachea. It should be remembered that flat opaque bodies always lie in the coronal plane when in the esophagus and in the sagittal plane when in the larynx. The most common location of foreign bodies in the esophagus is on a level with the clavicles. Opaque foreign bodies are usually easily demonstrable. Semi-opaque or non-opaque bodies offer much difficulty. In order to disclose the presence of a partially opaque or non-opaque body it is necessary often to rely on indirect evidence. The patient is given first a thin and then a thick barium mixture and its behavior is watched fluoroscopically and checked with roentgenograms. A foreign body may manifest itself by (1) a slight hesitation of the medium, (2) a forked stream such as is seen in benign tumors, (3) an actual filling defect, (4) a retention of the medium in a pocket about the foreign body, (5) spasm. Small balls of cotton wool impregnated with barium and swallowed without mastication may stick on the foreign body and disclose its presence and location. This procedure may interfere with the esophagoscopy examination if it should be necessary.

#### ACHALASIA OF THE CARDIA. (CARDIOSPASM)

Recent writers on this subject have been concerned with the choice of a name conformable with the newer knowledge regarding it and the pathology of the condition. The term "cardiospasm" has been virtually discarded. It has been demonstrated by the esophagoscope that the obstruction is not spasmodic. Moreover hypertrophy of the cardiac sphincter does not occur as would be expected were it due to spasm. The name "preventriculosis" has been used by Jackson (2), since, as he says it implies a location proximal to the stomach; an anatomical fact; it omits all implication as to etiology. Hurst (3) realizing the meaninglessness of the term "cardiospasm" asked Sir Cooper Perry to invent a name. He suggested the word "achalasia" which means absence of relaxation. The term has come into quite general use. The pathological findings are of particular interest. It was first suggested by Hurst (3) that possibly it was not a purely functional condition but was the result of organic change involving the neuro-muscular control of the sphincter. Rake (4) in 1925 was the first to demonstrate a round cell infiltration in Auerbach's plexus at the lower end of the esophagus. In a number of other cases degenerative changes resulting in more or less complete disappearance of the ganglion cells were found. These findings have since been confirmed by other investigators. The evidence is therefore quite convincing that achalasia is the result of organic changes in Auerbach's plexus. Mosher (5) feels that the primary factor is infection of the contiguous organs extending into the esophageal walls and producing fibrosis.

Dysphagia is the most prominent symptom but may not be recognized by the patient as such. He may be able to swallow but often does not realize that the swallowing act has not been completed. He may feel that food lodges in his throat. Other common findings are retrosternal fullness, regurgitation, and gaseous eructations.

lowed by odonophagia, dysphagia, aphasia or drooling at the mouth. The history may be misleading, particularly in children, and in all suspected cases a roentgen examination is advisable as a routine procedure. The presence of a foreign body in the esophagus is not ordinarily an indication for hurried action. Ulceration and perforation occur in many cases but a foreign body may remain in the esophagus for some time without causing complications. Foreign bodies with a sharp edge may perforate early unless removed. It is important to know how long the foreign body has been present but unfortunately the history is not always reliable.

Almost every conceivable object has been found in the esophagus. We observed one patient who had swallowed a package of safety razor blades which passed readily through the alimentary canal. Barclay (1) mentions a case in which a patient swallowed his week's wages, inconveniencing only the landlord who had to wait for his rent. Most foreign bodies which pass the esophagus will pass through the intestinal tract without difficulty if the patient is kept on his regular diet and bulky foods and cathartics are avoided. Objects most frequently lodged in the esophagus according to Jackson (2) are (1) bones, (2) coins, (3) safety pins, (4) artificial dentures, (5) buttons. In all of the instances in which bones, foods, coins, safety pins and buttons were found 95% of them were in the esophagus and the other 5% in the larynx and trachea. On the other hand 97% of the straight pins were found in the larynx or trachea.

*Roentgen examinations* in these cases should include everything from the nasopharynx to the ischial spines. Roentgenograms should be taken in various planes. Often a foreign body can be visualized only in the oblique position. Lateral views are particularly help-

The diagnosis cannot be made from the history but depends upon the roentgen and esophagoscopy findings. Both methods of examination are important and neither should be omitted.

The roentgen findings are quite characteristic. Preliminary examination of the chest may show a straight line shadow to the right of the heart and mediastinum. Fluoroscopic examination with an opaque meal shows the medium to float down the esophagus in parallel cords or as falling snow flakes. This appearance is due to the presence of fluid or food which has been retained in the esophagus. The medium stops above the cardia as a V-shaped constriction with smooth sharp outlines which come to a fine point. The esophagus above this point is usually dilated, sometimes to such an extent that it will hold large quantities of food and fluids. The walls are usually smooth and sharply defined but may show localized constrictions and bulgings due to peristaltic activity. The peristaltic waves may be reversed at times. In protracted cases the

esophagus becomes elongated, in some instances as much as 10 centimeters. The lengthened esophagus bends on the diaphragm to the right and ventrally and may as a result produce a rounded instead of a V-shaped border at its lower end. The ultimate evacuation of the medium is interesting. It may be vomited; it may pass into the stomach in small spurts during the expiratory phase of respiration, or may be moved into the stomach in a whole column without any evidence of constriction at the cardia. Twenty-four hour retention in the esophagus is not uncommon.

#### NEW GROWTHS OF THE ESOPHAGUS

There are many types of primary neoplasms of the esophagus but carcinoma is by far the most common. Carcinoma manifests itself in three forms; (1) epithelioma, which arises from the surface epithelium, is more frequent in the upper two thirds, is more prone to ulcerate, and has a tendency to perforate into the trachea, lungs, or mediastinum; (2) adenocarcinoma, which arises from the cells of misplaced gastric mucosa, is more frequent in the lower third, rarely ulcerates, and there is no tendency to perforate; (3) infiltrating type, in which the esophagus takes the form of a thick walled tube throughout its entire extent resembling linitis plastica and fibro-carcinoma of the stomach.

If the mortality of carcinoma of the esophagus is to be reduced below 100% early diagnosis is imperative

and recognition of the early symptoms is therefore essential. Jackson (6), after the study of a large number of cases, found the earliest symptoms to be vague and "neurotic" in character. The most frequently noted early symptoms were a slight queer feeling in swallowing, a feeling of nervousness before swallowing, vague sensations about the neck, a cramped feeling in the neck, a feeling that there is something wrong with the act of deglutition, or a sticking of food in the throat when eating rapidly. Dysphagia is always a late symptom and in some cases may not be present at all. The sudden onset of dysphagia in some instances is perplexing. The symptoms may date back only a few days or a few weeks and for this reason spasm may be suspected. It should be remembered that the sudden onset of dysphagia in carcinoma of the esophagus is not of uncommon occurrence. Pain is a very late symptom. It may not be so severe as in peptic ulcer or esophagitis and is found only in those cases where there is extensive ulceration

of the growth or an associated esophagitis.

Unfortunately the roentgenologist seldom sees this disease until it has run at least half of its course. In those cases where the early symptoms are suggestive and in which the routine roentgen examination shows no abnormality, the patient should be given some sort of irritant such as toasted bread crumbs or grated pineapple in order to bring on spasm which may be the only clue to the presence of a lesion. Esophagoscopy examination in these cases is

Fig. 2. Achalasia of the cardia. Note elongation and tortuous contour of the lower esophagus.

imperative. The roentgen appearance of the more advanced lesion is well known. As the patient swallows the opaque medium an abrupt hesitation is noted. It flows down to one side of the midline trickling over a ragged irregular defect. The outline of the growth may be detected in some cases. Dilatation of the esophagus above the lesion is usually not marked. Occasionally two defects may be noted in the esophagus or one in the esophagus and one in the stomach. Such double lesions are usually the result of extension through the lymphatics either from the esophagus to the stomach or from the stomach to the esophagus. Rarely do two primary lesions occur. Paralysis of the diaphragm is a late sign. Enlargement of the mediastinal glands in an adult is always an indication for thorough examination of the esophagus, inasmuch as a small neoplasm of the esophagus may cause extreme enlargement of these glands. Erosion of a malignant ulcer with per-

Fig. 3.

Fig. 3. Cicatricial stenosis of the esophagus resulting from the swallowing of lye. Note the large portion of the esophagus involved.

foration into the trachea is not uncommon. We have seen three such cases during the past year. It is always startling to see the lower bronchial trees fill with the barium mixture. Perforations are said to occur also as the result of abscess, syphilis and tuberculosis (Jackson) (6). Neoplasm may be confused with achalasia of the cardia (cardiospasm). Usually the age of the patient, the shorter history, and irregularity of the outline in neoplasm will differentiate the two.

#### ESOPHAGEAL ORIFICE HERNIA

Herniation of a portion of the greater curvature of the stomach through the diaphragmatic orifice is in general of two types which have not been clearly differentiated in recent roentgenological literature. In the first type the hernia may be as large as 10-12 centimeters in diameter; it is fixed and permanent; it is usually demonstrable in the upright position, and there is an associated congenital shortening of the esophagus. The second type is associated with the name of von Bergmann (7) who in 1932 clearly differentiated it from the first type. This variety of hernia is usually small, not more than 2-3 centimeters in diameter; it is not usually fixed but recurs when the patient assumes a horizontal or bending forward position; it is not demonstrable in the upright position, and to be visualized it is often necessary to increase the intra-abdominal pressure and examine the patient while drinking the opaque meal lying on the back. In this type, the esophagus is usually normal in length and a portion of the terminal esophagus may also herniate through the hiatus with the stomach.

An idea of the frequency with which esophageal orifice hernia occurs may be obtained by the experience of the authors. During the past few years they have seen as many of these hernias as all other esopha-

geal lesions combined. True it is, that they have looked for them in all examinations of the alimentary tract. Patients are observed both in the upright and horizontal positions both prone and supine at various angles and during deep and rapid respirations. Such measures are necessary in order to bring out the recurrent type. In many cases the hernia may be apparent for only a moment under the fluoroscope and may not be demonstrable at all on the roentgenogram.

In our experience this lesion has been found most commonly in middle aged or elderly women who are usually overweight and have considerable abdominal fat and a "cow horn" type of stomach.

The symptoms are often bizarre and may vary considerably in different cases. They may simulate those of duodenal ulcer or gall bladder disease. In other cases where the symptoms are more typical, esophageal hernia may be suspected. Several of our patients have been unable to assume a recumbent position without distress for several hours after eating a heavy meal. Some have found it necessary to take their evening meal a few hours earlier than usual in order to avoid retrosternal fullness and discomfort upon retiring. Dysphagia often is a prominent symptom particularly when the sack is large. The recurrent type may be suspected when pain or vague upper abdominal symptoms occur particularly at night or on bending over. The attacks in most cases are mainly nocturnal and disappear when the patient is up. Pain may occur just below the ensiform immediately after swallowing and in some cases may radiate to the arm and simulate angina. Occasionally the symptoms are so slight that they are elicited only on careful questioning. In some cases there are no symptoms and the discovery of the hernia is merely incidental to a thorough examination.

The roentgen appearance is characteristic in most cases. Before swallowing the opaque meal, a gas bubble may be noted in the hernial sac. As the meal is swallowed one notices first a slight delay at the cardia. Next, a compression defect appears on the concave side of the gastro-esophageal angle. At the same moment a pouch is visualized in this same area filling from below. The pouch is always situated just above the esophageal orifice and above the diaphragm. Many times when the pouch fails to fill completely, folds of gastric mucosa may be seen passing above the diaphragm through the hiatus. The recurrent type does not fill in the upright position. If this lesion is suspected it is advisable to observe the esophagus as the patient swallows the meal while lying on the back. Too drastic measures should not be used to increase the intraabdominal pressure. Filling the colon with gas and heavy compression may in themselves produce hernia and if complications are present, as is not unusual, serious damage may be done.

#### COMPRESSION STENOSIS

In the earlier stages of esophageal compression an organic lesion is often not suspected because of the vagueness of the symptoms. The roentgenologist is not consulted until the disease has run a protracted course.

Fig. 4. Barium in the right lower bronchus and inflammatory changes in the right lower lobe resulting from overflow from a paralyzed esophagus. The basic lesion was a chronic progressive bulbar palsy.

Roentgen examination of the chest will usually disclose the presence of an abnormal mass within or about the mediastinum. Examination of the esophagus with an opaque medium may reveal either a displacement or a filling defect depending upon the part of the esophagus involved normally. The esophagus is attached at both ends and sags somewhat in the midportion like a loose string. It can be readily seen that extreme pressure at or about the midportion will result primarily in displacement. Compression at one or the other points of attachment will produce a smoothly outlined defect simulating an intraesophageal mass. In those cases where displacement occurs the roentgen appearance can best be described by comparing it with that normally produced by the aortic arch. The esophageal shadow is decreased in circumference as the result of a smoothly outlined defect on the concave surface. The shadow of the compressing mass is often apparent and is in relation with the esophageal defect.

The most frequently encountered compressing lesions of the esophagus are as follows: (1) Aneurysm. Compression may result either from the saccular or dissecting types. The walls of the esophagus may become eroded and perforation may occur. (2) Abscess. Pyogenic or tuberculous retropharyngeal abscess may cause forward displacement of the trachea and esophagus and interfere considerably with the act of deglutition. A lateral view of the neck should always be a part of the roentgen examination in children who complain of dysphagia. We have been able to recognize retropharyngeal abscesses on several occasions before they have been discovered clinically. (3) Enlarged glands. Glandular enlargement causing esophageal compression may be the result of malignant lymphoma, leucemia, tuberculosis, syphilis, pyogenic infections or metastatic neoplasm. One should be particularly careful in such cases not to overlook a primary neoplasm of the esophagus. The widespread metastasis to the mediastinal glands in carcinoma of the esophagus may produce a pressure defect and may direct attention away from the primary growth. (4) Abnormalities of the great vessels. The dysphagia which may be the result of congenital displacement of the subclavian artery, transposition of the vessels or enlargement of the pulmonary conus incidental to a patent ductus arteriosus is known as "dysphagia lusoria." These are rather uncommon lesions and should be thought of in association with dysphagia of obscure origin. Extreme dilatation of the aorta may result in compression of the esophagus. (5) Cardiac enlargement. The extreme dilatation of the left auricle as seen in mitral stenosis often compresses the esophagus posteriorly or to the right to the extent of causing dysphagia. The authors recently observed a patient whose chief complaint was dysphagia incident to mitral stenosis. (6) Substernal thyroid. This condition should be differentiated particularly from benign intraesophageal tumor. These two conditions may not be distinguishable roentgenologically and esophagoscopy is necessary in doubtful cases. (7) Mediastinal and lung tumors. Any of the large group of malignant or benign tumors of the mediastinum or lung

Fig. 4.

may compress the esophagus. (8) Spinal deformities. Extreme lordosis or bony productive lesions arising from the ventral surfaces of the vertebral bodies may compress the esophagus and cause dysphagia. (9) Enlargement of the left lobe of the liver. Primary or secondary tumor masses, abscesses or cysts of the left lobe of the liver may compress the lower esophagus. (10) Mediastinal or mesial effusions. In these lesions the esophagus may be compressed over a considerable extent of its length.

The differential diagnosis of these various compressing lesions of the esophagus is not within the scope of this paper.

#### ESOPHAGEAL DIVERTICULA AND PHARYNGEAL POUCHES

Diverticula of the esophagus rarely cause symptoms. They are usually small pouches attached to the esophagus by a thin neck and do not retain the barium for any length of time. The pulsion type arises from pressure from within the lumen and is usually associated with an esophageal stenosis below the opening. The so-called traction type is the result of localized pulling on the esophagus from adhesions. The esophagus must be already fixed in order for a diverticulum of this type to develop.

The pharyngeal type on the other hand may cause marked symptoms. There may be a sensation of incomplete swallowing, fullness in the neck and difficulty in emptying the pouch. Roentgen examination shows a semicircular sac with a smoothly outlined convex border below and a horizontal fluid level above. The medium flows over the top into the esophagus as the sac empties. In the smaller pouches, the opening into the esophagus can be seen to lie just ventral to the upper border of the sac.

Fig. 5.

### CONGENITAL ATRESIA

This condition, which is an endodermal developmental defect, is usually seen during the first few days of life. The inability of the infant to retain food, the complete regurgitation of the small amount taken, choking, coughing and cyanosis are characteristic findings and from these symptoms the diagnosis can often be made clinically.

Malformations of the esophagus are not particularly rare. We have seen three cases during the past year. The types of malformation vary from complete absence of the esophagus to a partial stenosis. The most frequently encountered types lie between these two extremes and take the form of a blind upper and lower pouch which do not communicate with each other, but either one or both of which may communicate with the trachea through a fistulous opening.

Roentgen examination is important for verifying the clinical impression, determining the site of obstruction, the degree of occlusion, and the presence or absence of communication with the trachea. In order to visualize the esophagus it is often necessary to insert a small rubber catheter and inject the barium slowly under fluoroscopic observation. The point of obstruction, which is usually just below the bifurcation of the trachea, appears as a rounded, smoothly outlined border with moderate dilatation above. If none of the medium is seen to trickle down beyond the constriction, the obstruction may be considered to be complete. The abdomen should be examined for the presence of gas in the intestines and stomach. If present it may be assumed that there is a communication between the trachea and the lower esophageal segment.

The mortality in cases of complete obstruction, either with or without communication with the trachea, is 100%. The child dies within a few days from aspira-

Fig. 5. Benign tumor of the esophagus. Note the forked stream.

tion pneumonia. The importance of recognizing the degree of occlusion and the relationship of the esophagus to the trachea cannot be over emphasized in view of a statement by Jackson (8) in which he says: "The yielding of congenital stenosis to peroral esophagoscopic treatment is quite usual in those cases in which there is no communication between the esophagus and the trachea or bronchus."

### PARALYSIS OF THE ESOPHAGUS

Paralysis of the esophagus is not a rare condition. We have seen several cases and many cases have been observed by others.

The muscles of the pharynx, soft palate, larynx, tongue or esophagus may be involved as a sequence to diphtheria, cranial nerve neuritis, bulbar lesions or myasthenia gravis. Recently we had occasion to observe the esophagus in a case of myasthenia gravis and found that the medium behaved much the same as in other neuromuscular anomalies. One of our associates, Christie (9), has recently reported a case due to chronic progressive bulbar palsy and has pointed out the fact that the roentgenologist is often in a position to direct attention toward the possibility of a neuromuscular lesion. Other bulbar conditions which may result in dysphagia are syphilis, hemorrhage, and the bulbar type of poliomyelitis. Brahdy and Lenarsky (10) have recently reported a large series of acute poliomyelitis in which dysphagia was often a distressing symptom. In most cases relief occurred within a week. This is, they point out, to a great extent consistent with the course of bulbar lesions in general. The majority of them either progress rapidly to cause death or improve in a short time.

Roentgen examination in these cases discloses a complete stoppage of the meal in the posterior pharynx and the first portion of the esophagus without definite evidence of constriction. The medium is waltzed about in the posterior pharynx and overflows into the pyriform sinuses and often into the larynx and may fill the lower bronchial tree as in one of our cases. It may be washed down by drinks of water but still clings to the pharyngeal recesses and to the walls of the upper third of the esophagus. If it reaches the lower two-thirds of the esophagus it seems to pass through readily. This is interesting in view of the dual nerve supply to the esophagus. The upper third, which contains striated muscle, is nerved by the ninth and eleventh nerves through the nucleus ambiguus, whereas the non-striated muscle fibers of the lower two-thirds are nerved by the tenth nerve through its dorsal nucleus.

Relaxation of the laryngeal musculature may result in symptoms of dysphagia and give the same roentgen appearance as esophageal paralysis. This condition was first described by Quinke (11) and was called "laryngeal ptosis."

### CICATRICAL STENOSIS (TRAUMATIC)

The swallowing of corrosive poisons such as household lye and cleansers is by far the most common cause of scar tissue constriction of the esophagus. Such accidents occur most commonly in children.

Progressive dysphagia is the most prominent symptom. It may not develop for months or even years

Fig. 6. Syphilis of the stomach resulting in back pressure dilatation of the esophagus.

after the initial injury. Periods of almost complete inability to swallow may alternate with periods when there is no difficulty. Such symptoms are often misleading, and may result in an erroneous diagnosis unless careful attention is directed to the history. Occasionally corrosives may pass through the esophagus without injury to this organ but may cause a pyloric stenosis.

The lower and middle portions of the esophagus are most often involved and from one to two-thirds of the tube may be stenosed. This is accounted for by the fact that when the corrosive is swallowed the cardiac orifice closes reflexly and the column of liquid remains in the esophagus for a short time.

The roentgen examination is a valuable aid in disclosing the presence of the lesion, its location and extent and differentiation particularly from carcinoma. The esophagus above the stenosis is usually widened and sausage shaped. The medium trickles down from the most dependent portion in the midline as a very fine needle like stream. The strictured portion is usually of the same diameter throughout but occasionally one or more localized dilatations may be observed. In those instances where the stenosis occurs in the upper third the appearance may simulate that of a diverticulum. In the latter condition however, the stream is seen to overflow to one side whereas in stenosis it passes downward from the most dependent portion of the globular shadow. Carcinoma may cause some confusion, but is usually distinguishable by the jagged, irregular appearance of the outline. The roentgen appearance of benign strictures is fairly characteristic but the differentiation of the various types cannot be made from the roentgen appearance alone.

#### ESOPHAGEAL VARICES

The first case of esophageal varices in which the roentgen characteristics were described was that of Wolf (12) in 1928. Since then two cases have been reported by Hjelm (13), two by Beutel (14), five by Schatzki (15), and one by Kirklin and Moersch (16). At a recent meeting of the American Roentgen Ray Society, Holmes and Schatzki reported a large series of cases. We have had occasion to observe one case.

Dysphagia is rarely a prominent symptom. Attention is first directed to the alimentary tract because of hematemesis. Gastric ulcer or cancer is usually suspected clinically.

The varices are best demonstrated by using a thick barium mixture. They appear as semicircular defects interspersed with lace like areas of increased density, the latter representing the medium in the crevices between the veins. The roentgen appearance may simulate that of carcinoma but closely resembles that of multiple polyps. The presence of cirrhosis of the liver is confirmatory evidence of the nature of the lesion.

#### THE DYSPHAGIA OF ANEMIC WOMEN

##### *(Plummer-Vinson Syndrome)*

This condition which has sometimes been referred to as the Plummer-Vinson (17) syndrome, was, first described by Kelly (18) and Paterson (19) but without details as to the type of anemia present. In recent years this syndrome has become well recognized particularly in England. Hurst (3) has seen a consider-

108

Fig. 6.

able number of cases and papers have been written on the subject by Pyle (20), Jones (21) and Owen, Suzman (22) and others.

The syndrome occurs most commonly in middle aged women and is characterized by anemia, glossitis and dysphagia. The anemia is usually of the hypochromic microcytic type and is rarely primary. Achlorhydria or hypochlorhydria may be present. Atrophic glossitis is a constant finding and is similar in all respects to that found in the primary anemias. The glossitis may extend to the mucous membrane of the pharynx and first portion of the esophagus. Plummer and Vinson (17) considered the dysphagia as an hysterical manifestation but Hurst (3) feels that it is due to incoordination of the muscles which initiate deglutition consequent to a disturbance in the neuro-muscular mechanism. The pharyngo-esophageal sphincter which is normally closed does not relax after the food has been propelled into the pharynx by the tongue, thus resulting in retention of food in the posterior pharynx.

Roentgen study of these cases shows no abnormality of the esophagus. There may be a slight delay of the meal in the posterior pharynx.

#### BENIGN TUMORS

Moore (23) has made the statement that benign tumors are pathological curiosities. The reports particularly in the roentgen literature would so indicate.

Glandular retention cysts are found occasionally at autopsy but produce no symptoms and are not demonstrable on roentgen examination. Polyps are the most common benign tumors of any practical importance. They may be single or multiple and are usually attached by pedicles to the anterior wall of the esophagus behind the cricoid cartilage. Sometimes a polyp may be forced up into the mouth during the act of

vomiting and may be bitten off by the patient. Several such instances have been recorded. Spontaneous evulsion of other types of benign tumor occurs. Fibromata, lipomata, hemangiomata and myomata have been found in the esophagus. Pape and Spitznagel (24) have reported two interesting cases of myoma of the esophagus. In one the tumor, which was 5 cm. in diameter was situated in the first portion of the esophagus and was mistaken for a substernal thyroid. In the other the tumors were multiple and were situated in the lower esophagus, some of them projecting on pedicles into the stomach.

Benign tumors may produce marked dysphagia with typical signs of stenosis.

The roentgen findings depend to a large extent upon the type and size of the tumor. Small polyps which are attached by a pedicle may not be demonstrable. Large tumors show a characteristic forked stream with a defect in the center as the medium passes down either side of the tumor. A tangential view may disclose a semilunar, smoothly outlined defect. Non-opaque foreign bodies produce similar appearances, as do also extraesophageal lesions which are in contact with the esophagus at its attached ends. Esophagoscopy is necessary in such cases in order to arrive at a correct diagnosis.

### PEPTIC ULCER OF THE ESOPHAGUS

The apparent rarity of peptic ulcer of the esophagus in the roentgen literature is perhaps due to the fact that the lesion is seldom recognized. Jackson (25) in 1929 reported having seen twenty-one active ulcers and the scars of sixty-seven healed ulcers in 4,000 endoscopic examinations. Friedenwald, Feldman and Zinn (26) have been able to recognize thirteen cases in their practice. Other investigators have recorded smaller numbers and many single cases have been reported.

A description of the symptoms in most of the cases agrees quite closely. Although dysphagia is not often noticeable the patient becomes afraid to eat because of pain and regurgitation. The pain and discomfort usually appear beneath the sternum during the taking of solid foods and occasionally a half hour or more after meals. Alkalis usually give relief. Hematemesis is a frequent complication and may be fatal. Perforation into the mediastinum, pericardium or peritoneum is the usual cause of death.

The ulcer is usually single. It is situated on the posterior wall in the lower third of the esophagus just above the cardiac sphincter. It varies in size from a few millimeters to ten centimeters in diameter. It has all of the macroscopic and microscopic characteristics of chronic ulcer of the stomach or duodenum.

The most constant roentgen manifestation in the cases reported has been spasm. This was true of several of Jackson's cases and its importance as a diagnostic sign has been particularly stressed by Barclay (1). Friedenwald and Feldman (26) are the only authors who have succeeded in visualizing the crater of an esophageal ulcer roentgenographically. These same authors have described four types of defect in the ulcerated esophagus: (1) mucosal erosions, which are not as a rule demonstrable roentgenographically but may show spastic phenomena or a "fleck"; (2) niche or penetrating, which resembles the niche of a penetrating gastric ulcer; (3) spastic defects; (4) per-

forating, which is rarely observed roentgenographically because of the extreme illness of the patient.

### THORACIC STOMACH

This uncommon congenital defect is often associated with inability to take food in satisfactory amounts. True dysphagia is not a prominent symptom.

Roentgen examination shows the presence of a short esophagus proportionate to the high position of the stomach. The esophagus does not pass through the diaphragm and the stomach is always above the diaphragm. The duodenum usually passes through the diaphragmatic hiatus occupying the normal position of the esophagus. These features serve to distinguish this condition from the more common herniation of the stomach through the diaphragm.

### SYPHILIS

Guyot (27), in 1931, collected from the literature fifty-seven cases including two of his own of tertiary syphilitic lesions of the esophagus. Eleven of these were confirmed at autopsy. Fifteen others were recognized endoscopically and were said to have been cured by specific therapy. Thus less than half of the cases reported have been proven to be syphilitic.

We have had no personal experience with this condition. All suspected syphilitic lesions of the esophagus which have come under our observation have eventually been proven to be carcinoma.

Progressively developing dysphagia is usually the chief complaint. In the more active stages the symptoms may simulate those of peptic ulcer of the esophagus or non-specific esophagitis. As the ulcer heals, the lumen gradually becomes narrow and constricted and at this time dysphagia may be quite marked.

There is no characteristic roentgen pattern in syphilitic esophagitis. The presence of a gumma cannot be detected either by roentgenograms or the esophagoscope. In the diffuse type with stenosis the defect may simulate that of a new growth or if more extensive may be identical with cicatricial stenosis. The diagnosis cannot be made from the roentgen findings alone. The history, esophagoscopy, serological examination and the therapeutic test are all necessary in arriving at a diagnosis.

### TUBERCULOSIS

Tuberculosis of the esophagus is practically never observed by the roentgenologist because it occurs usually in the terminal stages of pulmonary tuberculosis. Small mucosal erosions may occur as the result of swallowing tuberculous organisms, but the ulcers rarely assume the characteristics which they do in the lower ileum and cecum. Areas of ulceration may result from extension from bronchial lymphnodes, the trachea, the dorsal vertebrae or even the lungs. Roentgenologically these ulcers cannot be distinguished from non-tuberculous ulcers.

It should be remembered that the dysphagia which is a common symptom in advanced pulmonary tuberculosis is usually the result of ulceration of the epiglottis.

### ESOPHAGITIS

Acute esophagitis is frequently the result of trauma from the swallowing of corrosives, but may occur also in blood stream infections even to the point of ulceration. Acute inflammation of the esophagus is not uncommon in pneumonia.

Chronic esophagitis according to Mosher (5) is a fairly common condition. It heals by depositing fibrous tissue and consequently is capable of producing stenosis. This same author has shown convincing evidence that cirrhosis of the liver and infection of the gall bladder are the chief predisposing causes of infection of the esophagus. He states further that fibrosis of isolated areas is fairly common particularly associated with arteriosclerosis. Jackson (2) feels that the most common cause of chronic esophagitis is stasis of food and secretions incidental to a stenosing lesion. He mentions strong alcoholic beverages, mustards, pepper and hot foods, hasty gluttonous eating and poor mastication as contributing causes. He has noted the frequent appearance of chronic esophagitis in all stenosing lesions of the esophagus, particularly marked in achalasia of the cardia.

Dysphagia is not a prominent symptom in chronic esophagitis unless there is some stenosis. The most common complaint is a vague dull ache behind the sternum which may radiate to the back.

The roentgen appearance in acute esophagitis shows no variation from the normal. As a rule roentgen and esophagoscopy examinations are contraindicated in the acute stage. Chronic esophagitis cannot be recognized roentgenologically as such and can only be surmised as a possible factor in stenosing lesions.

#### MYCOTIC STENOSIS

Actinomycosis and blastomycosis of the esophagus deserve only passing attention because of their extreme rarity. The roentgenologist may not see a single case in a life time and then only after stenosis has occurred.

The roentgen appearance does not differ from other stenosing lesions and the diagnosis can be made only by bacteriological examination.

#### DYSPHAGIA ASSOCIATED WITH GASTRIC LESIONS

Back pressure dilatation of the esophagus with relaxation and incompetency of the cardiac sphincter may result from (1) hour glass contraction of the stomach from the scar of an old peptic ulcer, (2) linitis plastica or fibro-carcinoma of the stomach with marked narrowing of the lumen, (3) operative intervention when there has been an extensive resection of the stomach. The swallowing of a large amount of air has been observed in one of our cases as a cause of dysphagia. The patient in question gave a history which was suggestive of a new growth. Roentgenologically the esophagus showed nothing abnormal. The patient swallowed such large quantities of air that the stomach became extremely dilated, and symptoms of dysphagia ensued.

#### HERPES, URTICARIA, ANGIONEUROTIC EDEMA, SERUM SICKNESS

These uncommon diseases have been described and included under one heading by Jackson (28). The lesions are quite similar in all and manifest the same characteristics in the mucous membrane of the esophagus as in the mucosa of other parts of the body and on the skin.

The diagnosis can be made only with the esophagoscope. Nothing abnormal can be noted either fluoroscopically or on the roentgenograms. The authors have had occasion to examine roentgenologically two patients who had urticaria of the skin and mucous

membrane and complained of difficulty in swallowing. In neither was there any demonstrable abnormality of the esophagus. The lesions in the esophagus are usually associated with lesions elsewhere on the body and these findings together with the esophagoscopy appearance are conclusive.

#### SPASM OF THE ESOPHAGUS

Esophageal spasm is usually the result of ulceration of the mucosa or the presence of a foreign body, but may occur without any demonstrable lesion as in a case reported by Grier (30).

The history may be of assistance in differentiating an organic from an idiopathic spasm. In the organic type the degree of spasm may vary with the same type of food or may actually disappear from time to time, whereas in the idiopathic type the spasm is usually more marked and persistent.

Spasm may take the form of (a) a B-shaped incisure, as is frequently seen in peptic ulcers of the stomach; (b) a concentric constriction as is seen in prepyloric gastric spasm; (c) a V-shaped narrowing.

The presence of esophageal spasm is always an indication for esophagoscopy study.

#### ATONY OF THE ESOPHAGUS

This entity has not received much attention in the roentgen literature. It was described first by Von Rosenheim (28) and the X-ray characteristics have been established by Holzknecht (29) and Olberta. It is a functional disturbance of the musculature of the esophagus which may cause mild or severe dysphagia.

During the act of swallowing, fluoroscopic examination reveals the medium clinging to the walls of the esophagus throughout its entire length where it remains for some time before going into the stomach. There is no evidence of stenosis. The roentgen appearance differs from that of esophageal paralysis in that in the latter there is regurgitation into the posterior pharynx and the medium clings to the walls only in the upper third rather than throughout the entire length.

Atony of the esophagus is found particularly in people with a neuropathic constitution.

#### GLOBUS HYSTERICUS AND HYSTERIA

Many patients who complain of dysphagia are told by a physician that their trouble is the result of "nerves," and this without more direct methods of examination. Such a conclusion is usually not only erroneous but dangerous. It is true that dysphagia which may be purely functional is not uncommon in neurotic patients but it should be remembered that there is no reason why a neurotic individual may not have an organic lesion in the esophagus. We believe that all patients who complain of dysphagia should have roentgen or esophagoscopy examinations or both unless the reason for the dysphagia is otherwise apparent.

Dysphagia as a manifestation of hysteria is extremely rare. Globus hystericus which is probably not a definite entity is more common.

Nothing abnormal is noted roentgenologically in these functional conditions. Barclay (1) believes that there is a definite causal relationship between calcification of the thyroid cartilage and globus hystericus. Such calcifications are seen so commonly without symptoms that it seems more probable that the association is merely a coincidence.

## ABSTRACTS

BOLES, RUSSEL S., AND GERSHON-COHEN, JACOB.

*Intestinal Tuberculosis: Pathologic and Roentgenologic Observations. J. A. M. A.*, 103:1814, Dec. 15, 1934.

In a series of 1000 consecutive autopsies, tuberculosis of the lungs was found in 226 cases. In these 226 cases of active and healed pulmonary tuberculosis an ulcerative type of intestinal lesion occurred in sixty-three cases. Primary hyperplastic tuberculosis of the large bowel was not observed in these 1000 autopsies.

A study of the relationship of the type of pulmonary lesion to intestinal ulceration shows the highest incidence in the fibro-ulcerative cavernous type of pulmonary disease. It may also occur in cases of early or exudative pulmonary tuberculosis. It occurred more frequently in women of the Negro race between 20 and 40 years of age. No cases of ulcerative tuberculosis were found in chronic fibroid or miliary tuberculosis.

The double contrast enema is recommended as an important aid in the diagnosis of ileocecal tuberculosis. It is claimed that this diagnostic aid will make early recognition possible and therapy may be instituted early.

Francis D. Murphy, Milwaukee, Wis.

KANTOR, JOHN L.

*Regional (Terminal) Ileitis: Its Roentgen Diagnosis. J. A. M. A.*, 103:2016, Dec. 29, 1934.

The author reports the roentgenological findings in six proven cases of the regional or terminal ileitis.

In the roentgen diagnosis of this condition the standard opaque meal is used. Observations are made hourly from

the period just before the cecum is filled to the normal period of ileac emptying.

Abnormalities are found in the colon and ileum.

In the colon the changes are due to reflex spasm. This spasm may involve the entire colon but more characteristically, the cecum alone. These changes are not constant. Actual involvement of the colon by adhesions or fistulae may occur. In such a condition a fixed deformity results.

In the ileum occur the most important changes. These consist of a constant defect in the filling of the terminal ileum; proximal to the filling defect the ileum showed an irregular shape or a peculiar taper point. Obstruction occurred in the small intestine proximal to the filling defect in two cases. The most striking finding is a thin, slightly irregular linear shadow extending from the region of the last visualized loop through the entire extent of the filling defect and ending at the ileocecal valve. This so called "string sign" represents the attenuated barium filling of the greatly contracted intestinal lumen.

In the differential diagnosis the appendix shadow must not be confused. Spastic segments of small intestine may be differentiated because of their wider lumen, denser shadow, smoother outline and variation in the location of the loops in subsequent exposures.

The "string sign" of regional ileitis remains constant even for days.

Tuberculoma, stenosing sarcoma and syphilis of the terminal ileum must also be considered in the differential diagnosis.

Francis D. Murphy, M.D., Milwaukee.

## SECTION VIII—Editorial

The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Association is in no way responsible for editorial expressions.

### THE CONCEPT OF "COMBINED ACIDITY" IN GASTRIC JUICE STUDIES

IN a recent article by Lay Martin (1) concerning the significance of the combined acidity of gastric juice, the Author concluded: "It seems wise to abandon the common conception of the expression 'combined acidity' since, in the first place, it is erroneous as it is applied, and, in the second place, open-minded recognition of the buffer strength of gastric juice between pH 4.0 and 8.0 may lead to further investigations of significance." For many years, clinicians and investigators concerned with the problems of gastric chemistry have measured both free and combined acidities. Conclusions concerning gastric secretory activity and its correlation with other physiological or pathological phenomena have, for the most part, been based on the value for "free HCl," or on that for "total acidity." Interpretations of the "combined acidity" value found in the literature consist simply of a statement of random variations in the amount of soluble protein present.

This lack of interest in "combined acidity" derives from several sources. In the first place, the values are generally small as compared with the experimental errors involved in their determination, and consequently their quantitative reliability is open to question. Secondly, the physiological significance of such values—particularly as this bears on problems of clinical importance—is still an open question. As Michaelis pointed out some time ago (2), the combined acidity value is influenced by the concentration not only of soluble protein, but also of phosphate and lactate ions, and the source of these constituents of the gastric juice has not as yet been clearly defined. Finally, our knowledge concerning buffer curves and the importance of pH in contradistinction to titration acidity is a relatively recent product of modern physiological chemistry.

Now, abandonment of the older conception of "combined acidity" is, to my mind, highly desirable, not only because the idea is chemically indefinite, but because of its sterility as a physiological concept. There can be no doubt that the buffer substances contained in ordinary gastric juice, the presence of which result in this "combined acidity," are physiologically of great importance. As I have shown in my own studies of gastric secretion in dogs, the pure parietal secretion—uncontaminated by other secretions or foreign substances—contains practically no buffer salts (3). On the other hand, the admixture of mucus or other alkaline secretion from the gastric mucosa with this HCl-containing fluid will result in the presence of such

"combined acidity." In fact, there probably exists a statistically definable quantitative relation between the magnitude of the "combined acidity," the relative amount of these alkaline secretions, and the reduction in acidity which results from their presence.

Having demonstrated that fluctuations in gastric acidity result from a variation in the amount of these buffer-containing secretions, rather than from a variation in the HCl concentration of the parietal fluid itself, it follows that some adequate quantitative measure of the buffer substances in gastric juice is of importance both clinically and experimentally. In consequence of his own work with gastro-globulin and other protein-like constituents of gastric juice, Dr. Martin proposes that we substitute for the combined acidity, as it is determined at present, the exact titration value between pH 4.0 and pH 8.0; *i.e.*, to endpoints which are determined by comparison with standard buffer solutions. This would certainly constitute a well-defined measure of the buffering power of the gastric juice in this pH interval. In my own work (4), I have employed a similar procedure, though the pH interval chosen was slightly different, the range extending from 3.5 to 7.0. On the other hand, Michaelis recommended pH 2.8 as the lower limit of this range and Shohl and King (5) employed 3.0. Any one of these procedures will yield a well-defined measure of the total buffer content of gastric juice, and as such they are all worthy of consideration. Furthermore, they require no physico-chemical technique beyond the capacity of the ordinary clinical technician, although they do demand somewhat greater care in their performance than that usually given a gastric titration. It must be remembered, of course, that such a determination of gross buffering power will not tell us anything about the distribution and characteristics of the various buffer substances present. This information can be derived only from a complete titration curve over an even more extensive pH range. Although the time and labor required for the determination of a buffer curve are so great as to prohibit the utilization of this method for routine clinical work, these should be no drawback for experimental purposes, nor should the technical demands on training and equipment constitute a hindrance in any modern physiological laboratory. The fruit of such effort will more than justify the labor.

In conclusion, it seems to me that some official recognition should be taken of Dr. Martin's recommendation regarding the abandonment of the classical notation of "combined acidity." As for a substitute procedure which "may lead to further investigations of significance," any decision in this regard should come from a body designated to consider the matter from its various aspects, clinical as well as experimental. Such a group, acting under the authority of the American Gastro-enterological Association, might consult very extensively with individual workers throughout the country. A report of the varied opin-

"For a splendid review of present day information as to the toxicity of vitamin D, the reader should turn to an article on the Physiology of the Sterols, including Vitamin D by Charles E. Bills in *Physiological Reviews*, 15 (1):1-98, 1935."

ions so obtained would, at the very least, stimulate further thought on the matter, and might possibly furnish a new and well thought-out procedure to replace the present one for determining "combined acidity."

Franklin Hollander, New York, N. Y.

## IS THE PUBLIC BEING STAMPEDED IN REGARD TO VITAMINS?

**T**HE other day I saw a woman with indigestion and a nervous breakdown. The story was puzzling until the husband explained, feelingly, that at each mealtime his wife wrangled with the children over the eating of spinach and carrots and the taking of cod liver oil until everyone at the table was exhausted and in a bad humor. Was this necessary? Will the children of this fairly well-to-do, middle-class American family come to grief if the mother stops stuffing them? I think the chances are that they will not.

*How did people "get by" before vitamins were discovered?*

Certainly when I was a child my mother knew nothing of vitamins, they had not yet been discovered; and yet today I stand six feet in my stockings, and my legs are straight. How did I and millions like me grow strong and well in the old days? Simply because we had a varied diet and enough of it. We had fresh food; most of us in this country had milk and butter and eggs and fruit, and we did not need cod liver oil because we spent much of our childhood out of doors in the sun.

While I do not wish to minimize the value of modern dietetic research and its splendid discoveries, I still feel that we are passing through a stage of experimentation in which vitamins are being forced on children and adults without sufficient thought and understanding. The historically minded man cannot help remembering that every substance ever found useful in the prevention or cure of disease once had to go through a stage during which it was given for everything. In each instance enthusiasm slowly waned, and eventually, the more enlightened type of physician saw clearly when and when not to use the substance. In many cases, it turned out that the drug should never have been used at all.

*Is enough as good or better than a feast?*

Certainly most of us will be better satisfied about the use of vitamins when research workers are able to tell us how much of what is learned from experiments on rats is applicable to man, and particularly to adult man. Already we know that the rat does not react to the lack of vitamins in all respects as man does; he can make at least one of them himself somewhere in his body. Perhaps this explains the fact that a research worker, who, a few years ago, found the diet of Mexican children in our Southwest decidedly insufficient, according to standards based on experience with rats, had to admit that the children seemed to be about as large and as healthy as their better fed playmates whose parents came from the North. Incidentally, individual men react differently to lack of vitamins. As every polar explorer knows, in the old days some men promptly succumbed to scurvy while a few seemed to be almost immune.

We physicians also want to know how much of the several vitamins must children and adults get every day to remain in health? We are only now beginning

to get a little information in regard to this, and some people are beginning to see that what is needed by the child may not be needed at all by the adult. We want to know, also, if it does any good to keep stuffing a child with vitamins after it has enough. May not enough be as good as a feast? Recently, I saw a woman with indigestion and a number of curious symptoms produced apparently by the taking of a quart of orange juice a day. Unfortunately, the pyorrhea, which her dentist had hoped to cure with an overdose of vitamin C, was still present.

It may well be that there is a number of diseases that can be cured with the help of large doses of some one vitamin, but I cannot help looking with a little scepticism on some of the enthusiastic papers that are now being published. Usually the work is not done so that one can be sure that vitamins alone produced the improvement noted in the patient; and, again, the historian reminds us that the easiest road to the front page of scientific magazines has always been through the reporting of startling cures obtained with a new and popular therapeutic agent. As I said before, when the excitement quiets down, it is found, sometimes, that the germs that the new drug was supposed to kill thrive on it, and physicians must wonder then how certain papers came to be written.

*Vitamin D in large doses is a poison*

We know that large doses of vitamin D will kill an animal in a short time, and we know that smaller doses injure the arteries. Under these circumstances, it is well that several research workers are trying to fix the upper limit of safe dosage. Fortunately, evidence is accumulating to show that the injurious dose is so much greater than the useful one that under ordinary circumstances no one need worry.\* But, unfortunately, today circumstances are not ordinary, and we may have to fear two tendencies: one, that of people to go to extremes, and the other, that of present day manufacturers of foods to add too much vitamin D to their products. Today the desire of purveyors of food and popular drugs to advertise that their product is full of vitamins is so strong that they may go too far and something may have to be done to restrain them.

Let us imagine a child who, to begin with, does not need extra amounts of vitamin D because he is out in the sun all day. He is getting all he needs in his food, and his bones are growing straight and strong. But his well-intentioned mother is forcing on him large doses of the very powerful, irradiated ergosterol; he is getting more "D" in his pint or more of irradiated milk; the cows which supply the milk are being fed yeast and other substances to increase the vitamin content of the cream and butter; the baker is adding "D" to his bread, and, as I write, manufacturers of breakfast foods and chewing gum, and even cough drops, are all hastening to join in the race.

Personally I rather resent having to take unasked-for vitamin D every day simply because the men who supply me with food want a new selling point. I see the advantages of supplying extra vitamins to the children of the poor, but when I, an adult, decide to stuff myself with such a powerful drug as vitamin D, I would rather have some control over the process, and I would rather get my supply from the drug store.

\*For a good review of some of the literature, see Reed, C. I., Symptoms of Viosterol Overdosage in Human Subjects. *Jour. Am. Med. Assoc.*, 102:1745-1748, May 26, 1931.

If present practices keep up, I fear that before long the government will have to step in and say that vitamin D may be added, let us say, to milk and/or bread, but not to other foods. I understand that the owners of the irradiation patents are worried over the situation and are refusing huge sums offered for new licenses. But this will not prevent manufacturers from adding vitamin D in other ways.

Fortunately, as yet, none of the other vitamins seem to be hurtful when given in large doses.

#### *When vitamins are needed*

The worried housewife should be taught that vitamins are so largely concerned with growth that they are most important to the pregnant woman, the nursing mother, and the growing child. In adult life, and when there is no extra stress, such as that of pregnancy, lactation, or prolonged illness, they are less important, and there seems to be little reason for forcing them on people who are already living on a liberal and well-chosen diet.

Although I would not think of denying the safety value to growing children of milk, eggs, fresh fruit, green vegetables, and cod liver oil, I think we should sometimes remind worried mothers that some of the healthiest, huskiest, fattest children, with the most perfect teeth, are to be found among the uncivilized Eskimos who never saw a cow, a hen, a fruit, or a vegetable. Living almost entirely on meat and fish, they get their vitamins by eating much of the food raw, and particularly by eating the inner organs, such as liver, kidneys, and marrow.

I would like to show a group of these healthy Eskimos to every enthusiast who insists that the only way to health is through eating spinach, or wholewheat, or orange juice. I would like him to see that there is no one indispensable or perfect "Nature food." He should learn that the defect in one food can easily be compensated by the special richness of another. For instance, white flour is certainly deficient in vitamins; but the baker adds so much milk and yeast, and now vitamin D, and the eater of the bread spreads so much butter on his slice, that it is silly to worry about the loss, during the milling; of the little wheat germ and its contained vitamins.

If we, in this country, were living on bread alone, the government might well pass a law making wholewheat compulsory for all bread making, but in view of the fact that our children can so easily get, and are getting, their vitamins from foods other than wheat, anyone who would advocate such a law would only expose his ignorance of the science of nutrition.

#### *The thoughtlessness of forcing growth stimulators on the girl babies of overly-large parents*

One thought that does not seem to occur to people is this: if several of the vitamins are primarily stimulators of growth, are physicians and intelligent, well-read, and conscientious mothers, really using their brains when they force large doses of these substances on the already oversized children of oversized parents? Such stuffing with vitamins may be all right for the girl babies of people who are short in stature, but is it not rather thoughtless when the father is six feet four and the mother five feet ten?

Already many of our boys in this country are too tall for comfort in the standard chair, bed, theater seat, or Pullman berth. As I travel about the country I am impressed with the number of girls I see who

are so tall or so big in every way that they are embarrassed and unhappy, and their chances of marrying are diminished. During the last century, every generation in this country has tended to be a little taller than the preceding one; it would seem that a reasonable limit has been reached, and I doubt if we really want to go on producing huge men and, particularly huge women.

#### *Does the giving of vitamins prevent colds?*

One of the sales' arguments for giving vitamin A has been that it will prevent colds or make such infection milder. Although some experiments on animals and children suggested that this might be true, two reports of controlled studies on two groups of persons, one given extra amounts of vitamins and the other not, now show that these substances cannot be counted on to influence respiratory infections.

#### *Disease due to avitaminosis is probably rare in American adults*

The medical profession would probably do well to point out to the worried dietitians and mothers of families that disease which can be definitely ascribed to avitaminosis is very rarely seen among American adults of the middle or upper classes. Even the physician with a very large practice will see only a few cases a year in which he will suspect that the symptoms are due to too great a narrowing of a diet. Usually, such a patient is old: he may be a recluse who cooks for himself, or a psychopathic food crank who is fussy about eating and is full of prejudices, or he may be a red-nosed bum who has been trying to live on whiskey. Not infrequently the victim is a patient with peptic ulcer or ulcerative colitis who has been living too long on milk and little else.

It is interesting also to note that evidence is accumulating to show that, at times, and perhaps particularly in the case of non-tropical sprue and pernicious anemia, a disease due to the lack of certain substances in the food may be brought on by the failure of the intestine to absorb properly. At times, disease may appear only when to avitaminosis there is added another factor such as infection. This is thought to be the case in beriberi.

#### *It is not necessary to give rough foods in order to supply vitamins*

Advertisements in the magazines and the propaganda of food faddists have given many laymen the idea that the foods rich in roughage and vitamins are the most digestible and health-giving. This view must be combatted, and at times it must be pointed out to people that, especially when they are suffering with indigestion, they can easily obtain desired vitamins without eating a lot of indigestible cellulose-containing food. They can now buy vitamins in a concentrated form at the drug store.

#### *The dangers of sensitizing infants and children*

Sometimes I wonder if the present tendency to feed infants with foods formerly reserved for children and adults is having anything to do with what seems to be a tremendous increase in the incidence of hay fever and other disorders of allergic origin. There are reasons for believing that the intestinal mucous membrane of the infant is more permeable to foreign protein than is that of the adult. If this be true, we are probably sensitizing many children who in the old days of

breast feeding or milk formulas would never have suffered with allergic troubles. Doubtless this is only one cause of the increase in allergic diseases, because it seems probable that with the cultivation of enormous areas of the land, there has gone a big increase in the growth and distribution of those weeds whose pollen is so hurtful.

Certainly many of the sufferers from allergic disease seen today were born before the era of spinach and orange juice, but if it should appear later that part of the increase in the incidence of allergic disease is due to the sensitization of infants and children by too early stuffing with foreign protein, then we will have to avoid this; and if in that future day we still desire to give overdoses of vitamins, then, at least in the case of the children of allergic parents, we will have to give the vitamins and salts in pure form as is now done in the case of dietetic research with rats.

Unfortunately, as yet, it has not occurred to many people that one does not have to sensitize a child to orange juice in order to give him a milligram of ascorbic acid, nor does one have to stuff him with eggs or spinach in order to supply a little iron. Incidentally, Rohmar, Bezsonoff and Sanders now claim that an infant up to the age of fourteen months can make his own vitamin C.

A great artist was once asked with what he mixed his paints. "With brains, Sir," was the answer. Let us more often mix our prescriptions with brains: with real thought of exactly what we do and do not want to accomplish in the individual case.

#### Summary

Those persons who are now stuffing themselves or others with vitamins are not always well informed or logical in their behavior. As always happens with new therapeutic agents, vitamins are now being used to cure many diseases. As yet one cannot tell how much of the information obtained with rats should be applied directly to human beings, and especially to adults.

Vitamins are largely stimulators of growth and hence they are of value mainly to the growing child, the pregnant woman, and the nursing mother.

Information is still needed as to the adequate dose of the various vitamins for children and for adults. It is important to know whether or not it helps to stuff more vitamins after enough have been given. Since vitamin D is a lethal poison, we should know exactly the upper limit of safe dosage. It looks now as if the addition of vitamin D to foods will soon be overdone. If every purveyor of foods adds it to his product some children may get too much.

Those enthusiasts who get too excited about the necessity for forcing particular foods, such as orange juice or whole wheat, should keep in mind the uncivilized Eskimo with his perfect teeth, his chubby children, and his diet of fish and seals.

It is suggested that it may be undesirable to stuff girl babies of oversize parents with powerful stimulators of growth. Already many American girls are too tall for comfort.

Recent clinical trials have cast much doubt on the assumption that the giving of vitamin A will prevent colds.

Results of a careful questionnaire indicate that the leaders of American medicine rarely see disease due definitely to avitaminosis in middle class or even poor adult men and women.

It should be pointed out to laymen that one does not have to eat rough and indigestible foods to get vitamins and mineral salts. The daily ration of these substances can now be bought in the drug store in the form of a pill.

The question is asked if an apparently great increase in the incidence of allergic disease may not be due in part to the present-day practice of stuffing infants with foods for the handling of which their delicate intestinal mucosa is not yet ready.

Walter C. Alvarez, Rochester, Minnesota.

#### DR. SIBRAND LUPS' MONOGRAPH CONCERNING "CHRONIC ULCERATIVE COLITIS" AND AN APPRECIATION OF ITS TRANSLATION INTO ENGLISH BY DR. ABEL J. BAKER

TO all of our readers, undoubtedly, will come profit and pleasure from the printing of Dr. Sisbrand Lups' original studies concerning the bacteriologic factor in the etiology of "chronic ulcerative colitis."

The research has been conducted in a masterly and unbiased fashion; the data are presented excellently; illustrations and tabulations vividly tell their own stories. Moreover, this Journal's publication of Dr. Lups' studies is the first appearance of the work in the English language—a printing copyrighted by the Author.

While to Dr. Lups' and his European publishers our grateful thanks are given for permission first to reprint the work in English and to use the original copper plates for the beautiful illustrations, our major indebtedness goes to the translator, Dr. Abel J. Baker, Grand Rapids, Michigan.

When Dr. Lups' monograph and its accompanying illustrations reached us, an immediate—and for a time—puzzling-problem presented, namely that of adequate translation by a *trained, capable internist*. "Translation hacks," commonly laymen, easily are located, but such translations as they return lack those very necessary scientific values to words and phrases which only can be given by a physician and scientist. Even on the faculties or staffs of our most widely known schools of medicine, clinics or hospitals, it was not possible to uncover the person whom we felt the task demanded: an internist of standing who also was scientifically solid and who, though an American, read (and could think in) "Holland Dutch" as a language twin to his American.

In this quandary, happily the Editor recalled the capabilities of a former class-mate, Dr. Baker. Not a little time was consumed overcoming Dr. Baker's well-known modesty and claims as to his inability to bring to the task of translation a full degree of scientific adequacy. We were sure of his ability; our chief concern was that one so thoroughly occupied in professional consultations never could spare the time needed for so formidable a job. Eventually, all arrangements were made and the translation submitted. How thoroughly and faithfully Dr. Baker has performed his task, the printed article demonstrates far more eloquently than could any words of ours.

Finally, just the degree of indebtedness which our readers and the management of the Journal owe Dr. Baker perhaps can be appreciated when we set forth here that not alone did the Translator devote many valuable hours to the work but that, personally, he bore every penny's expense concerned with steno-

graphers, typists and the multitude of "incidentals" which pile up during a task of this nature!

Formal thanks, of course, have been transmitted to Dr. Baker. Such seem to carry scant weight compared with the work performed—the sacrifices of needed rest, recreation, other reading, even the financial burden. Whatever may be the individual tributes which readers "on their own" may transmit to Dr. Baker is their concern and responsibility. However, we at the Editorial Office acknowledge most gratefully that the Translator removed from our shoulders a heavy editorial burden and from our "counting house" (and from those of several presumably dollar-strong institutions to whom ineffectually we turned for financial aid for this particular piece of work) a load which in these times could not be sustained.

Further Dr. Baker has given American medical literature a contribution which not alone most eminently is worth while but he has allowed physicians and scientists of these Western lands a glimpse of what investigative efforts are being carried on by such well grounded, careful students and clinicians as are connected with the institutions of Holland: a land whose medical men and scientific literature, alas, we know but too vaguely—not alone because few of us read Dutch, but because Hollanders frequently seek their scientific audiences in German and French journals. Thus, they are apt to lose their national identity and that of their most admirably managed and equipped scientific institutions.

Frank Smithies.

## NOTICE

THE 38th Annual Session of the American Gastroenterological Association will be held under the Presidency of Dr. B. B. Vincent Lyon, Philadelphia, at Hotel Traymore, Atlantic City, New Jersey, on Monday and Tuesday, June 10th and 11th.

Not only has the Association prepared an unusually strong program for the coming meeting, but inasmuch as its session will be held immediately prior to the opening of the combined meeting of the American and the Canadian Medical Associations (the first of such gatherings) attendance at this annual meeting of the American Gastroenterological Association offers extraordinary opportunities to enjoy and to benefit from the co-ordinated social and scientific presentations of these great national organizations.

In an early issue, this Journal will print the complete program of the Association's sessions. Members of the Association who plan to attend this week of unusual scientific and clinical value would be wise if *immediately* they reserved hotel space. Indications are that "last minute" reservations will lead to disappointment. Already numerous prominent hotels are booked solid.

*Write the hotel of your choice at once.*

Russell S. Boles, Secretary,  
American Gastroenterological Association,  
Rittenhouse Plaza,  
Philadelphia, Pa.

## SECTION IX—*Book Reviews*

*(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).*

The Physiology of the Gallbladder by A. C. Ivy. Physiological Reviews, 14:1-102 (Jan.) 1934.

THIS comprehensive publication summarizes the present status of our knowledge of the physiology of the gallbladder.

The gallbladder manifests the principal general activities of the intestine, namely, absorption, secretion, and motor activity. Absorption, which is selective, consists chiefly in the abstraction of water and certain inorganic salts. The secretion is mucoid in character and its enzymatic content is insignificant. Motor activity is of the same general type found in the intestine, that is, propulsive and non-propulsive. The biliary ducts have secretory but little absorptive activity, and they may or may not manifest motility, depending on the species.

Absorption of water and inorganic ions by the gallbladder is accomplished according to the law that the gallbladder content tends to remain isosmotic with serum, as determined by the freezing point method. Experimental evidence indicates that the maximal rate at which water is absorbed by the gallbladder is about 6 c.c. per hour, leading to a concentration in animals and man of six to ten times the hepatic bile that enters the gallbladder. Concentrating ability, however, is limited and no greater concentration is found in forty-

eight than in sixteen to twenty-four hours. The wall of the gallbladder also absorbs sodium, chloride, and bicarbonate ions, with an increase in acidity of the bile as it becomes concentrated. It is of interest to note that anatomic evidence indicates only blood capillary tufts are present in the mucosal folds of the gallbladder, and consequently substances absorbed by the epithelium pass primarily into the vascular and not into the lymphatic system.

Evidence indicates that calcium is absorbed by the normal gallbladder; calcification of the wall of the gallbladder has been produced experimentally; and an injured gallbladder mucosa has excreted fluid containing calcium. Bile pigments are apparently not absorbed in appreciable quantities. Ivy concludes that the available evidence indicates that small quantities of bile salts may be absorbed by the normal gallbladder and that inflammation or irritation of the gallbladder increases the rate of absorption of bile salts. Evidence on the absorption of cholesterol is difficult to evaluate, but the data indicate that normal gallbladder mucosa absorbs relatively small amounts, if any, of cholesterol daily, and that the inflamed mucosa, because of its cholesterol content, may add cholesterol to the contents of the gallbladder by desquamation. The pathologic significance of this latter process certainly is open to further investigation. There is no evidence that bile fat passes through normal mucosa

of the gallbladder during the concentration of bile.

The effect of drugs and nerve influences on absorption of the gallbladder is indicated by the fact that stimulation of the vagus, peripherally, increases the rate of concentration, whereas stimulation of the splanchnic nerves decreases the rate of concentration. Atropine does not prevent normal absorption or normal concentration. Absorption of tetriodophenolphthalein from the gallbladder probably occurs at a slow rate. Evidence indicates that in cases of acute cholecystitis, concentrating ability is lost, as it is also in empyema, hydrops and secondary contraction of the gallbladder; in the papillomatous gallbladder with hypertrophied rugae, however, it is increased.

**Secretion.** Under normal conditions it may be said that the gallbladder forms only a small quantity of mucoid secretion, and that under conditions of acute irritation it ceases concentrating and pours out a fluid, which telologically may be compared to a type of catharsis.

**Motor activity.** Two types of motor activity are manifested by the gallbladder: (1) tonic contraction, which produces a sustained rise in pressure within the gallbladder, persisting for from five to thirty minutes or more, and (2) tonus rhythm, which is manifested by rhythmical contraction and relaxation, occurring at a rate of two to six times a minute.

**Innervation of the gallbladder.** Ivy and Schrager found that pain, vomiting, and respiratory disturbance result from distention of the gallbladder. Pain was abolished by splanchnic section, chiefly on the right; nausea and vomiting were abolished by section of vagus fibers, and respiratory disturbances were reduced by section of either the splanchnic or vagus nerves. In regard to motor innervation, evidence still indicates that although the vagus and splanchnic nerves carry motor and inhibitory fibers, the vagus nerve is preponderantly motor and the splanchnic nerve inhibitory for the gallbladder.

**Evacuation of the gallbladder.** Ivy believes that three types of evidence unequivocally demonstrate that evacuation of the gallbladder occurs in man by way of the cystic duct, namely, surgical evidence, chemical analysis of duodenal contents, and roentgenologic evidence. Fats and fatty acids are the most active evacuates, and proteins (meat) rank next; carbohydrates, on the other hand, are comparatively ineffective in causing evacuation of the gallbladder. According to Boyden, the lecithin fraction of egg-yolk is the most potent fraction, but pure lecithin is not so efficacious as crude. Liquid petrolatum does not evacuate the gallbladder.

Ivy states that he has failed to find in the literature a completely negative report of the effect on the gallbladder of magnesium sulphate insofar as "evacuation of the gallbladder is concerned, that is, a report in which a fairly large series of normal subjects was used and in which some evidence of evacuation was not obtained for some of the subjects studied. The story is different, however, in regard to therapeutic and diagnostic efficacy." The mechanism of action of magnesium sulphate still is not clear. The effect is apparently not produced by a humoral route and, although the theory of a reciprocal reflex mechanism is favored, insufficient evidence is available to answer the question satisfactorily. The consensus of opinion is that magnesium sulphate is not so effective as is egg-yolk or cream, or as olive oil and oleic acid.

Ivy points out that while a number of writers have referred to the hyperkinetic, vagotonic, sthenic, or hyperactive gallbladder, and to the hypokinetic, sympathotonic, asthenic, or sluggish gallbladder or to various types of gallbladder response, the evidence presented is not yet conclusive. There is, apparently, an intermittency in gallbladder evacuation in man. Boyden has referred to phases of contraction which follow a fairly definite sequence, and he has described three types of response of the gallbladder of man to stimuli. These consist of: (1) an initial relaxation of the gallbladder, with apparent simultaneous closure of the sphincter, (2) rapid evacuation due to contraction of the gallbladder and probably to relaxation of the sphincter, and (3) a sluggish type in which the initial phase of emptying is followed by filling and in which the time of evacuation is prolonged. His studies also indicate that in fifty normal persons the time of evacuation ranged from sixteen minutes to four and one-half hours; some observers, however, believe that it may be longer.

Mechanisms that have been suggested for excitation of the gallbladder include: (1) local stimulation by distention or "pungent" bile, (2) nervous reflex excitation from various parts of the gastro-intestinal tract, (3) reflex excitation from spinal cord and higher centers, and (4) humoral agents. The only possible interpretation of the evidence at hand is that a hormone mechanism is concerned in contraction and evacuation of the gallbladder, the hormone (cholecystokinin) being closely related to, but not identical with secretion. The problem of the rôle of duodenal motility and the sphincter of Oddi in evacuation of bile is still not settled. As Ivy states, although the gallbladder may evacuate without the assistance of the duodenum or sphincter of Oddi, one cannot avoid the fact that there exists an important choledochoduodenal mechanism for regulating the flow of bile into and out of the gallbladder. That duodenal motility and tone play a part in controlling the flow of bile into the duodenum is accepted as a fact by all observers. Evidence may also be interpreted to indicate that in those species with a gallbladder, the common duct possesses a special sphincteric mechanism which is intimately coordinated with duodenal tone and peristalsis but which may also function independently. It may be regarded as established that the sphincter of the choledochoduodenal mechanism is essential for the filling of the gallbladder. "In the relatively rapid type of evacuation of the gallbladder of man and dog which occurs after the ingestion of a meal of egg-yolk and cream or fat, the evidence shows that the chief factor concerned is a rise in intra-gallbladder pressure. This rise is due primarily to a more or less sustained tonic contraction of musculature. The contraction is excited in part by a hormone (cholecystokinin) and by reflex nervous mechanisms (cephalic or gastro-intestinal). The sphincter of Oddi and the duodenal musculature promote evacuation by relaxing and permitting bile to be expelled by the contracting gallbladder. The evidence shows that a reciprocal functional relationship exists between the gallbladder and the choledochoduodenal mechanism, but whether this relationship is reciprocally causal is an open question. The evidence also shows that duodenal peristalses are not essential for but assist evacuation."

In summarizing the evidence of the relation of disease of the biliary tract and gastric acidity, Ivy

states that it can only be said that there is a tendency in man toward anacidity which is not specific in character and has no appreciable significance in the diagnosis and symptoms of the affliction.

In summarizing the evidence on the rôle of the gallbladder in the function of biliary tract and digestion, Ivy states that the gallbladder serves as a "factor of safety" in digestion and in regulating the pressure in the biliary passages. In fact, there are indications that the pressure-regulating function of the gallbladder is more important than its function of storage of bile for digestive purposes. Ivy also believes that a search should be made for functions of the gallbladder other than those which have been enumerated already.

Dwight L. Wilbur, Rochester, Minn.

*The Automatic Diseases or the Rheumatic Syndrome*, by T. M. Rivers, M.D., Dorrance & Co., Philadelphia, 1934, pp. 299, \$3.00.

**T**HIS book contains a scholarly account of the autonomic nervous system together with a consideration of a variety of diseased states which are believed to be dependent, more or less directly, on abnormalities of this system. The author is a fellow of the American Medical Association residing in Kissimmee, Florida. Between 1923 and 1930 he published three or four papers dealing with the treatment of abrasions, contusions, and fractures. Since 1930 five articles have appeared from his pen in the "Journal of the Florida Medical Association." The titles of these suggest that they represent the basis of the present monograph. The author in his preface states that living in a small community and working in general practice he found his clinical material scarce; but instead of letting this hamper his efforts he tried to make it work to his advantage by giving more attention to the study of his cases. In conjunction with his clinical observations he attempted some laboratory work. Basing his efforts on the study of Barger of Edinburgh and others who had already determined that

the toxins of local infection were amines, he spent his spare time testing the action of various amines on membranes and joints of turtles, frogs, and guinea pigs, and learned that amines as well as other agents "sometimes pass their morbid action through the cranio-sacral nerves."

The book is interestingly written and the subject matter is well arranged. A number of misconceptions and erroneous statements of fact appear—for instance, that the distribution of lime salts in the body seems to be governed by vitamins A and D, and that products of metabolism, as creatin and creatinin, pass their augmentory action through the thoracic-lumbar nerves to produce hypertension and the diseases related to hypertension, and that an excess of carbon dioxide in the tissues causes the formation of excess uric acid, and that gout is due to excess of uric acid in the blood, and that painters develop gout from lead inhaled from their paints, and that vitamin D serves little if any purpose in the body development without the ultraviolet ray, and that death in most cases of angina pectoris results from intense spasm of the aorta, and that resection of parts of the colon is the most dependable treatment for epilepsy. On the whole, however, the broad conception that much disease of the rheumatic category depends on amines, acting principally on fibrous tissue by way of the cranio-sacral nerves, will deserve serious consideration if it ever comes to be proved that cranio-sacral nerve fibers pass into the muscles or the skin or the joints.

It is apparent from the 135 journal articles and 32 monographs named in the bibliography of his book that the author has read widely in this field. He has an inquisitive mind and the ability to correlate facts which to many would seem to defy correlation. That he is a very wise and skillful physician is indicated by the perusal of the chapter on heart affections. The delightful flights of speculative fantasy into which the subject of this book leads him are tempered throughout by a large measure of critical judgment.

R. M. Wilder, M.D., Rochester, Minn.

## SECTION XII—"The Clinic"

### Traumatic Duodenal Ulcer in a 10 Year Old Boy

By

JACK WITHERSPOON, M.D.  
NASHVILLE, TENNESSEE

**D**UODENAL ulcer due to external violence is looked on with skepticism but has long been recognized. Numerous cases, proven by autopsy, operation, X-ray and clinical history, are to be found in medical and medico-legal literature.

Chronic peptic ulcer may occur at any age. It is quite uncommon in children.

Fig. 1. "Pine Tree" Deformity Duodenal Ulcer in a Child.

#### CASE REPORT

We desire to present such a case in a 10 year old white boy, oldest of four children. He complained of cramping pains in the abdomen and under the ensiform cartilage, nausea, loss of appetite, loss of blood from the bowel, and loss of weight. In the latter part of September, 1934, six weeks before we saw him, he was playing during recess in the school yard. He was tripped, and fell on his abdomen, knocking the breath out of him. He was carried into the school house where he lay in the rest room for a while, then he was sent home. He did not vomit, but that night complained of nausea and pain in the

abdomen. His father, a school teacher, stayed up all night with him, rubbing his abdomen and applying hot packs to it. The next morning the patient passed blood from the bowel and for the next few weeks nearly every stool was black or contained blood. He developed anorexia and indigestion. A few hours after eating, cramping and burning occurred, followed by food relief. He frequently vomited and on several occasions vomited blood. The pain was not continuous, but when it occurred the little boy placed his hands on his stomach, and bent over and cried. Sodawater frequently induced vomiting, but usually gave relief. In six weeks he had lost about 12 pounds in weight. Prior to the passage of a bloody stool he was often weak, nauseated, and his temperature sometimes rose as high as 102°. He became quite weak, remained away from school for two weeks and on the bed most of the time.

His previous medical history is not important. He has had measles and chicken pox. He has not had tonsillitis nor any continued fever. There was no lack of C vitamin in his diet. Early last Summer, while visiting his grandmother, he ate a good many June apples and developed stomach ache and diarrhea. He was seen by a doctor who kept him in bed a few days until he recovered. There were a few recurrences of enteritis but he regained his weight and was in good health when school started.

Examination showed a thin, anemic, debilitated little boy, with a temperature of 100°, and pulse of a 100. His skin was dry and pallid. His throat, chest, heart, lungs and extremities were not noteworthy. A few superficial lymph glands were palpable. The abdomen was flat, the spleen and liver were not enlarged. There was tenderness in the epigastrium near the mid line below the ensiform cartilage. No mass could be felt. The area of tenderness was protected by marked rigidity of the recti muscles. Pressure caused nausea. There was no tenderness or rigidity about McBurney's point. The sigmoid

flexure of the colon could be felt and rolled but caused no pain. His urine showed a trace of albumin. Blood examination showed Hemoglobin 50%, red cells 3,500,000, and leucocytes 13,000. He had been sick in bed a week, and had vomited blood, and passed black stools.

Fluoroscopically the barium meal entered his stomach without delay. The

Fig. 2. Penetrating Juvenile Duodenal Ulcer with Spastic Pyloric Ring.

stomach was high and hypertonic. The pylorus was spastic. No filling defect or deformity was seen in the stomach. The stomach was filled. The first portion of the duodenum presented a constant filling irregularity similar to that seen in a duodenal ulcer in an adult. The deformity was close to the pyloric ring, and there was lagging of the barium in the base of the duodenal cap. A series of films showed a typical duodenal ulcer. No five hour examination was done, but in 24 hours all the barium was in the colon. The colon was hyperspastic.

Fig. 3. Traumatic Duodenal Ulcer (in a Child) with Adult-like Deformity.

### TREATMENT AND COURSE

He was given a modified Sippy powder, with paregoric and bismuth mixture as an antispasmodic. His diet consisted of frequent small feedings of milk, cream, buttermilk, cooked cereals and fruit juices. He did well for two weeks and gained four pounds, when he had a recurrence of diarrhea, probably due to too much magnesia in the powder. He began vomiting and he was brought back. In the hospital he vomited blood and passed stools containing dark blood. He recovered in a few days and is again on the treatment with less powder.

The symptoms of peptic ulcer in children vary with the age of the child. In the newly born, *melena neonatorum* occurs. These ulcers may be said to be acute, and in the age group from one to ten, the symptoms consist of bleeding, loss of appetite, digestive upsets, and occasional perforation. After the age of ten and particularly about puberty, the symptoms of night pain or pain relieved by vomiting, and pain late after meals relieved by more food, or alkalis, or vomiting, resemble the symptoms described by Moynihan. They have seasonal recurrence and pursue the same chronic course as peptic ulcer in adults. When examined the ulcers are found to be deep and round with indurated edges.

Trauma as a cause of peptic ulcer was first described by (1) Potain in 1856. He reported a woman, aged 60, who was struck in the abdomen by a heavy piece of furniture. After 8 years of a clinical history of ulcer, death occurred, and at autopsy a

large, indurated ulcer was found on the lesser curvature of the stomach associated with hour glass deformity.

Traumatic ulcer of the duodenum and the stomach is the subject of an interesting paper by Crohn and Gerendasy in a May, 1933 issue of the Journal of the American Medical Association. They say that there is almost no American literature on this subject but cite many foreign cases of proven traumatic origin.

In discussing the *etiology* they say

the trauma is always of a severe type: falls, violent compression injuries, vehicle accidents, blows from falling bodies, etc. They report the following case: "A man, 35, was struck in the abdomen by the hoof of a horse. A few days later vomiting began. Symptoms continued with increasing severity for one year, at which time gastroenterostomy was performed for a pyloric ulcer. A cure resulted."

The stomach is exposed to injury in the epigastric region where it lies

## ★ Peptic Ulcer Cases become symptom-free

### on the Larostidin Treatment ★

**THE** experience of clinicians who have tested this method shows that, in most instances, Larostidin affords prompt relief.

**After 5 days . . .** Pain usually disappears and does not recur. Nausea, vomiting, hyperacidity, and flatulence are relieved.

**After 10 days . . .** Normal diet well tolerated. Appetite improves. There is consequent gain in weight, general systemic improvement, and vastly improved mental outlook.

**After 24 days . . .** Radiologic findings, in many cases, become negative. Patient can usually be discharged from treatment.

### One daily injection Larostidin for about 24 days

AMPULS. 5 cc.  
Cartons of 6

\*4 boxes constitute  
one complete  
treatment.

The treatment consists of one daily injection of Larostidin for about 24 days.

Larostidin is a 4% solution of lacro-histidine monohydrochloride, supplied in 5 cc. ampuls.

Intramuscular injections are best; the preferred sites for injection are the arms and the gluteal regions.

BULMER, in reporting his results in 52 cases of peptic ulcer (*The Lancet*, Dec. 8, 1934) emphasized the fact that the Larostidin treatment is better than the older methods—alkalies, feedings, etc.—in bringing about complete subsidence of symptoms, and that these results are easily achieved with ambulatory management. Dr. Bulmer's paper was abstracted in the *Journal of the American Medical Association*, February 23, 1935, page 690.

1. Potain, A: *Bull. Soc. anat. de Paris*, 31: 353, 1856.

**HOFFMANN-LA ROCHE . . . Nutley, New Jersey**

within the costal angle, but below the protective border of the liver.

Posteriorly the stomach lies directly in front of the rugged vertebral column. When the stomach, especially when full of food, is pinned between the vertebral column and some obtruding body, or is subjected to great traumatic force, a rupture in the mucosa may readily occur.

(2) A widow, age 44, had been previously free of digestive disease. In February, 1930, when riding in a public conveyance (bus) she was forcibly thrown against the sharp edge of the forward seat on the opposite side of the aisle. The fall was a violent one due to the front wheel of the bus striking a culvert. She was able to proceed home and next day had vague epigastric distress and passed black stools. In twenty-four hours she was nauseated and vomited blood. She had hematemesis and melena for several weeks following. Physical examination showed a contused area below the 9th costal cartilage on the right side. Two weeks after the accident duodenal ulcer was demonstrated by X-ray examination.

**THE PORRO BIOLOGICAL LABORATORIES**

718 Medical Arts Building,  
Tacoma, Washington.

It is of interest that the New Jersey Supreme Court in October, 1932, affirmed judgment in favor of the plaintiff.

There is much speculation as to the *mode of ulcer formation*. In experimental work, chronic peptic ulcers are hard to produce and occur only when certain factors are present. Violent trauma is certainly not the cause of a majority of peptic ulcers but it is suggested by many writers that milder degrees of trauma, external or internal, may play a part when changes in secretion, changes in motility or in the nervous mechanism are favorable for the formation of chronic peptic ulcer.

*Pathologically*, traumatic peptic ulcers are usually single, they are usually round, and occur close to the

pylorus, though many have been found about the lesser curvature. They begin as a mucosal or sub-mucosal hemorrhage with laceration of the walls of the stomach of varying degrees of severity. They are more often in the duodenum. Symptomatically, they run a chronic course with digestive symptoms like ordinary peptic ulcers.

Bleeding commonly occurs early in traumatic ulcer.

(3) Liniger and Molineus offer certain postulates that need be satisfied before a case of suspected traumatic ulcer may be accepted as a true example of such a lesion.

1. Proof must be given of the absolute absence of gastrointestinal

3. Liniger and Molineus, quoted by Gerendasy, Julius: *J. A. M. A.*, 21:1658, 1933.

## CELLU Canned Fruits

*Packed in water without added sugar*

**INCREASE THE CHOICE OF FRUIT  
IN THE LOW CARBOHYDRATE DIET**

### FOOD VALUE

Fruits packed in water without added sugar are shown by chemical analysis to have their carbohydrate content reduced from that of the fresh product. Lessening the carbohydrate content makes it possible to include these fruits in diets where fresh fruits might be prohibitive. We list the carbohydrate values of Cellu fruits here for convenience of comparison.

### CONVENIENT TO USE

Cellu Canned Fruits not only increase the variety in the menu but add much to the convenience of food preparation. Saccharine may be added to these fruits if desired.

complaints or symptoms prior to the accident.

2. The trauma must be a severe one and localized to the abdominal wall, preferably to the epigastrium.

3. The immediate onset of symptoms must follow the injury.

4. The continuation of the developing symptoms and signs must assume the characteristics of a true gastric or duodenal ulcer.

The paper of (4) Crohn and Gerendasy is reviewed by Dr. Eusterman in the Medical Year Book. (5) Dr. Eusterman and Dr. Joseph G. Mayo report the following case: "A farmer boy, aged sixteen years, was brought to the Mayo Clinic in an ambulance March 18, 1932. Except for mild attacks of influenza and tonsillitis he had enjoyed excellent health until October, 1931, when he had fallen headlong from the back of a moving automobile, striking the epigastrium forcibly on an empty spare tire rack. He was knocked to the ground and was breathless for thirty seconds or longer. At that time

he had experienced no actual pain although there was some contusion of the upper left abdominal wall, and he did not feel well for the remainder of the day. Within twenty-four hours epigastric pain appeared and was most marked on exertion, so that he eventually was compelled to discontinue all work, attendance at school and participation in sports. Aggravation of the pain was not caused by taking food. Shortly after the injury he had had occasional left epigastric pain which appeared half an hour to an hour after meals, lasted for an hour or so, and disappeared before the next meal, so that he was always free of pain at meal time. Five months had passed since the injury, the above symptoms persisting off and on, when, after a day's heavy work on the farm, he had recurrence of epigastric pain and noticed tarry stools. On the two following days he was free of pain. Then the pain became more marked and was associated with thirst, massive hemorrhage from the stomach, syncope and shock. Following this hemorrhage the pain disappeared, and the boy was brought to the clinic.

The patient was pale, in a fair state of nutrition, with no abnormality other than anemia (hemoglobin 68 per cent, and erythrocytes 3,860,000 in each cubic

millimeter of blood) and moderate tenderness, without rigidity, in the left side of the epigastrium. Roentgenoscopic examination March 21, 1932, gave clear evidence of a penetrating ulcer on the lesser curvature, above the incisura angularis. Three days later, after administration of histamine, there was a great deal of secretion, maximal total acidity was 106 units, and free hydrochloric acid, 94 units (titration with tenth normal sodium hydroxide). Because the patient was young and the symptoms of recent onset, operation was deferred and intensive treatment undertaken. He was placed in hospital and made a favorable response. Successive roentgenographic examinations disclosed gradual diminution in the niche, and April 16, 1932, no defect was demonstrable. The boy was dismissed to follow a regimen for ambulant patients with an ulcer. He has been so well since that time that we have not been able so far to get him to return for reexamination although he lives just across the border of a neighboring state."

The above mentioned authors also discuss ulcer as the result of foreign bodies in the stomach and as the result of diaphragmatic hernia.

GRAND RAPIDS, MICHIGAN

### ULCERATIVE COLITIS; A CASE WITH AUTOPSY

*History of Illness:* The patient who was forcibly delivered of her fifth child on April 26, 1933, was admitted to the gynaecological ward on the 4th of May. For some time previous to her confinement she had complained of abdominal pain which gradually grew worse. Her abdomen was larger than it had been during any of her former pregnancies. In the last six weeks of her late pregnancy she had vomited a great deal. There was no particular history of malfunction of her bowels. In spite of the fact that she had lost a great deal of amniotic fluid, her abdomen remained very large *post-partum*. On the 28th of April she developed a temperature. There was very little lochia.

*Examination on the 4th of May.* The patient gives the impression of being seriously ill. Her tongue is moist, not coated. Pulse regular, normal size and tension. Heart and lungs normal. Abdomen is markedly distended, about the size of pregnancy at term. No peristalsis can be made out. Intestinal sounds absent. On percussion there is tympanites and the examination is painful. Palpation of solid organs is impossible because of distension.

*Vaginal examination.* Cervix admits two fingers. Externally the fundus uteri cannot be felt. As far as can be determined, the uterine cavity is empty. There were no tears present. The left appendages apparently are normal. On the right side, there was some resistance which seems to merge into the cervix. The pouch of Douglas was normal. There was no marked discharge. The urine is negative. Temperature runs up to 39° C.

The entire picture gives one the impression of a peritonitis with paralytic ileus altho the etiological connection with her parturition is not clear. She was given physostigmine and bowel irrigations. This treatment relieved her of much distension.

On May 5 her abdomen showed less distension and she passed much flatus. On May 6 her general condition was worse. She complained of severe abdominal pain and vomited everything taken by mouth. Meteorism was marked. Pulse was frequent and small. On May 7, she was continually losing ground. Her face was pinched, the pulse very poor and she was still vomiting. Tongue was red and dry. She was given "cardiozol," digalin and caffeine. Her respiration became more rapid, pulse imperceptible, hands and feet cold, and at 12:30 she died.

*Autopsy by Doctor Behr:* Section was made twenty hours after death and the findings recorded were as follows: On opening the abdomen much gas escaped; cecum, ascending colon and transverse colon were markedly dis-

(Continued from April, 1935, Issue)

tended and nearly filled the peritoneal cavity. The coils of the small bowel were also distended although not to the same degree. The serosa was dull with patches of hyperemia and fibrin formation. In spite of the fact that the abdomen contained much gas, there was no perforation found anywhere. About 500 cc. of cloudy free fluid was present. This had no odor. There were no fecal masses present. On removing the ascending colon for a complete inspection, this was torn under the liver and a mass of thin feces flowed into the peritoneal cavity. On opening the small intestine, the mucous membrane was found to be entirely normal. The cecum, ascending colon, and transverse colon, on the other hand, showed many ulcers with a yellow, rather speckled base. The size and form of these ulcers varied a great deal, ranging from a pinhead upward and were found mostly in groups surrounded by mucous membrane which was markedly injected and hemorrhagic in spots. Other ulcers were much larger and of irregular shape. Their greatest width was in the transverse diameter of the bowel. At the site of the ulcers, the intestinal wall was friable and easily torn. The serous aspect revealed many large streaks of fatty tissue. These were also present in the omentum which was adherent to the bowel. The mesenteric vessels were empty. The remainder of the various organs showed no particular changes and the uterus and parametrium were normal.

*Microscopic examination.* Ulcers from the ascending colon showed a complete loss of mucous membrane which was replaced by granulation tissue containing many leukocytes and cell debris, necrotic areas and bacteria. The *muscularis* revealed areas of necrosis. In some places there was marked infiltration of inflammatory nature. In the upper layers of submucosa were found leukocytes and numbers of large mononuclear (abnormal reticular cells) and plasma cells. Such were also found in deeper layers of the intestinal wall as well as large thrombosed veins. The serous aspect was covered with fibrin and leukocytes. Sections of other ulcers revealed similar findings.

Section of the mesentery showed extensive infiltration with many distended mononuclear cells, lymphocytes and a few polynuclears. The tissue was edematous and there was a marked lymphangitis. In some of the lymphatic vessels small cocci were present but whether these were diplococci we were unable to say.

The kidneys showed marked degeneration of the tubular epithelium. There were many small emboli (diplococcus) mostly surrounded by hemorrhages and masses of leukocytes which here and there amounted to small abscesses. The liver cells were swollen and there was much cell dissociation.

The spleen showed evidence of infection with edema and hyperemia of the pulp. There was marked infiltration with leukocytes. The uterine wall showed many thrombosed vessels but no evidence of inflammation.

From the tissue surrounding the ulcers in the cecum and colon, the *Diplococcus of Bargaen* was isolated in pure culture. These organisms were also present in large numbers in the base of ulcers.

#### ANIMAL EXPERIMENTATION BY BARGEN AND OTHER INVESTIGATORS

In 1924, Bargaen instituted bacteriological investigations on the material which he isolated from the intestinal mucous membrane of a number of patients suffering with ulcerative colitis. Culturally he found two varieties of microorganism, *gram-positive diplococci* and *gram-negative bacilli*. The diplococci were, but the bacilli were not again identified. (These might have been colon bacilli; Helmholtz and Beele). Inasmuch as it occurred to him that these organisms might possibly be the cause of ulcerative colitis, he carried out animal experimentation to determine their pathogenicity.

For experimental purposes, he used rabbits which had been fed exclusively on vegetables, oats, hay and water. In his first series he used 190 rabbits to which he gave intravenous injections of 2 to 5 cc. of a bouillon culture not over 24 hours old. Some of the rabbits he injected with a mixed culture of both bacilli and cocci, others with pure culture of the diplococci, and still others with a pure culture of the bacilli. Those animals which survived the injection were sacrificed at intervals of from one to 28 days. At autopsy a bacteriological investigation was made of the blood, the mesenteric glands, spleen and in some cases of lesions in the colon.

The results of these experiments were as follows: Of the 190 rabbits, 56 developed lesions in the colon consisting of hemorrhages and superficial ulcers. Of these 56, eleven had been injected with a pure culture of diplococci and 45 with a mixed culture of diplococci and gram-negative bacilli. In those animals injected with mixed culture, the intestinal lesions were more wide spread and were more severe than in those in which the pure cultures were used.

On closer study of the 56 rabbits of which 23 died spontaneously and 33 were sacrificed, it appeared that 38 had developed diarrhea with mucus and blood in the feces. In these, as well as in the others, Bargaen found at autopsy colonic lesions and bloody mucus in the feces. In addition to the lesions mentioned, he also found in 15 cases lesions in the ileum. In two he discovered abnormalities in the appendix, in one in the jejunum and in one in the duodenum. All organs in these 56 animals were examined, but except one kidney infarction and one case of hemorrhage in the lumbar muscles no other pathology was found.

In a few animals it was possible to isolate a pure culture of gram-positive diplococci from the mesenteric glands and in a very few from the spleen. Microscopic examination of the affected part of the bowel revealed gram-positive diplococci in the tissues surrounding the lesions. Other bacteria were present only on the surface of these affected areas. In the rest of the 190 experimental animals, 23 developed diarrhea but no discoverable lesions. Sixty-five had neither diarrhea nor any intestinal lesions. Seven developed swelling of the mesenteric glands only. The majority of these

rabbits were injected with cultures of the gram-positive diplococci.

In a number of rabbits, a pure culture of the gram-negative bacilli was injected. These rabbits died within 24 hours after the injection. Intestinal lesions were not found in these cases.

#### CONTROL EXPERIMENTS

In four patients who did not have ulcerative colitis but in whom rectoscopy was done because of hemorrhoids or other conditions, material from the mucous membrane of the bowel was taken for bacteriological examination. From this culture, four rabbits were injected; one of these developed diarrhea and at autopsy petechiae were found in the colon. In cultures from the other three patients, no diplococci were found. Intravenous injections of these cultures into the rabbits caused no bowel lesions.

The results of the first series of animal experiments on the etiology of ulcerative colitis may be summarized as follows: (1) Mixed cultures of the gram-negative "colon bacilli" and the gram-positive diplococci injected intravenously into rabbits, frequently caused lesions of the colon which resembled those which are found in patients suffering with ulcerative colitis. (2) Pathological investigation of the affected areas in the bowel frequently revealed gram-positive diplococci in the tissue surrounding the lesion. (3) Pure cultures of the gram-positive diplococci generally caused no lesions in the colon. (4) Pure cultures of gram-negative bacilli were fatal to the rabbits but caused no changes in the colon.

Bargaen explained the results of the experiments as follows: The gram-negative (colon bacilli?) probably caused the illness of the rabbits and in this way created a predisposition to the growth of the gram-positive diplococci. These latter diplococci should then be considered the true cause of disease. Bargaen was supported by Helmholtz and Beeler who were of the opinion that colon bacilli might cause edema of the cecum but never actual lesions. In 1925 Bargaen and Logan again experimented with 18 rabbits which had been kept for three weeks on a vitamin free diet. Nine of these animals were given 5 cc. of intravenous injections of bouillon cultures of a freshly isolated diplococcus. These animals were sacrificed within 5 days. Autopsy revealed that in eight of these, lesions in the colon had developed, ranging from submucous hemorrhages to small ulcers. Furthermore three animals also had empyema of the gall-bladder which contained a pure culture of the diplococcus. Of the nine animals which had not been inoculated, five died of malnutrition, while four lived for four months on vitamin poor diet.

Cultures of the diplococci obtained from the gall-bladder of those rabbits which had developed empyema were injected intravenously into young dogs. A daily injection of respectively, 12, 20, 20, 20, 20, and 30 cc. was given. Inasmuch as the lesions which Bargaen had obtained in his rabbit experiments must be considered more in the nature of an acute condition, he hoped in this manner to produce lesions which would more likely resemble those in the human individual suffering from chronic ulcerative colitis.

Many of the dogs developed serious diarrhea and indeed, on making rectoscopic examinations lesions were found resembling those in the human individual.

Bargaen thus succeeded in causing ulcerative colitis

in rabbits kept on a vitamin free diet with a pure culture of gram-positive diplococci. He also succeeded in producing colonic lesions in young dogs with the diplococci obtained from the contents of the diseased gall-bladder in rabbits which had been thus previously injected.

Fradkin and Gray duplicated the work of Bargaen with 4 rabbits. Each animal was given altogether from 40 to 50 cc. of a pure culture of the gram-positive diplococci intravenously. This quantity was given over a period from five to seven days. Two animals developed a frank arthritis. Two others developed diarrhea with marked proctitis. From the rectum of these, diplococci were isolated. These two died at the end of the fourth day. At autopsy dark red hyperemic spots were found in the large bowel. Also here and there pinhead-sized ulcers. The diplococci were found in large numbers in the submucosa of the affected bowel. The heart's blood, mucus from the colon and the gall-bladder also showed pure cultures of the cocci.

Rafsky and Manheim also carried out animal experimentation with the diplococci of Bargaen. They could not produce ulcerative colitis in rabbits. They injected two rabbits intravenously with 4 cc. of a bouillon culture of the organism. The animals developed neither diarrhea nor any other symptoms. Four weeks after injection, they were sacrificed, but at autopsy no anatomical changes were discovered. These experimenters also injected rabbits which had been kept on a vitamin free diet for two weeks with 5 cc. of a pure bouillon culture of the diplococci. These did not develop diarrhea although they lost weight, but remained alive. At the end of three weeks, they were sacrificed. At autopsy they showed no lesions in the colon and no anatomical changes elsewhere.

Gutierrez, Lastra en Blanco injected rabbits intravenously with pure culture of the diplococci of Bargaen. They were unable, however, to produce intestinal lesions, but when a mixed culture of the diplococci and other anaerobic intestinal bacteria was used, the rabbits developed diarrhea and died. At autopsy lesions were found in the colon. These investigators, however, on the basis of their experimentation, deny the etiological importance of the diplococci of Bargaen in producing colonic ulcerative colitis. Rather they feel that anaerobic organisms might have produced these in the animals.

Paulson believes that the animal experiments of Bargaen do not prove conclusively the *diplo-streptococci* to be the cause of ulcerative colitis. Neither does Basler attach to the diplococci of Bargaen any etiological importance.

#### EXPERIMENTAL WORK BY THE AUTHOR

In order to carry on our animal experimentation, it was, of course, absolutely necessary that we secure a culture from an actual case of ulcerative colitis concerning the diagnosis of which there was no question. Further, the diplococcus must necessarily be isolated from the ulcers themselves, inasmuch as similar organisms entirely resembling the diplococcus of Bargaen are sometimes found in the feces of individuals not having ulcerative colitis. For our experiments therefore, we made a culture which was isolated from the colonic ulcers of our case which came to autopsy. Of this material bouillon culture preparations were made and cultured for 24 hours at 37° C. In order to eliminate harmful associations of other bacteria, the cul-

ture was centrifuged. The clear upper layer was separated and replaced with physiologic salt solution in which the bacteria again were suspended. This was again centrifuged and the upper layers removed. This was repeated twice. Finally a concentrated emulsion in physiologic salt solution was used for animal injection. Further tests were made with emulsions of this culture after passage through one or more animals. In our experiments we used rabbits which were normally fed.

*Experiment with rabbit No. 1.* Weight 3 kg. 1½ cc. of the above diplococcus emulsion injected in the vein of the ear.

There was no diarrhea, sacrificed after 7 days. *Autopsy:* large bowel in some areas showed bloody mucous membrane. From the bowel wall material was taken and cultured. Diplococcus was positive. In the lumen of the large bowel a number of small cyst formations somewhat smaller than a green pea were present. The contents of these on culture show a pure strain of diplococcus. Small bowel is normal, gall-bladder filled but negative for diplococcus.

*Experiment with rabbit No. 2.* Weight 3 kg. 1 cc. of diplococcus emulsion injected into vein of ear, after passage through another rabbit.

There was considerable loss of weight but no diarrhea; sacrificed after 11 days. *Autopsy:* large bowel very hyperemic with much mucus. In two areas at the site of branching of the small blood vessels were found small grayish-white circumscribed elevations about 1 cm. in diameter. Small bowel normal. Gall-bladder filled, diplococcus positive. Peritoneal glands swelled, diplococcus positive. Spleen soft.

*Experiment with rabbit No. 3.* Weight 3 kg. 1 cc. of diplococcus emulsion injected into the vein of ear after previously passing through two rabbits.

Much loss of weight, no diarrhea. Died in 8 days. *Autopsy:* large bowel had much mucus. In one area at the site of small branching blood vessels were found grayish-white sharply circumscribed, rather round elevations with diameter 1 cm. From this tissue the diplococcus was cultured. Small bowel was normal. Gall-bladder was normal. Bile was negative for diplococcus. Spleen soft.

*Experiment with rabbit No. 4.* Weight 2 kg. 1 cc. original diplococcus emulsion injected into vein of ear. Rabbit became ill after 2 days with diarrhea and died after 8 days. *Autopsy:* large bowel markedly injected, and in the lumen much bloody mucus. Diplococcus positive. Stomach and small bowel show injected mucosa. Gall-bladder acutely inflamed. Diplococcus positive.

*Experiment with rabbit No. 5.* Weight 1¼ kg. 1 cc. original diplococcus emulsion injected into vein of ear. Much loss of weight. Ill in few days with diarrhea. Died after 7 days. *Autopsy:* mucous membrane of large bowel and cecum markedly hyperemic; some areas showed much bloody mucus. Diplococcus positive. Stomach and small bowel also were markedly hyperemic. Gall-bladder filled. Bile negative for diplococcus. Spleen soft.

*Experiment with rabbit No. 6.* Weight 1½ kg. 1 cc. original diplococcus emulsion injected into vein of ear.

After two days there was diarrhea and much mucus discharge. Died in 5 days. *Autopsy:* part of large bowel showed punctate hemorrhages. There was also much bloody mucus. Diplococcus positive. The remainder of the large bowel was also hyperemic, likewise the small bowel. Gall-bladder filled. Diplococcus positive. Spleen soft.

*Experiment with rabbit No. 7.* Weight 1 kg. 1 cc. original diplococcus emulsion injected into vein of ear. The rabbit was sick after two days with diarrhea and mucus discharges. Died in 5 days. *Autopsy:* mucous membrane and cecum showed much swelling and hyperemia. In the lumen there was much bloody mucus. Diplococcus positive. Small bowel hyperemic. Much mucus in the lumen.

Fig. A. Rabbit No. 14. A small focus containing tissue and cell debris found in an inflamed joint capsule. Much nuclear fragmentation. Oil immersion magnification reveals many diplococci.

---

---

Fig. B. Mucous membrane of colon; rabbit No. 2. Below the surface large accumulation of lymphocytes. Mucous glands are separated by widespread infiltration of inflammatory cells. Some areas show an entire absence of mucosa which is replaced by inflammatory infiltration containing many lymphocytes and leucocytes.

---

Gall-bladder normal. Diplococcus negative. Spleen soft. Diplococcus positive.

*Experiment with rabbit No. 8.* Weight 1 kg. 1 cc. original diplococcus emulsion injected into the vein of ear. There was diarrhea with bloody mucus discharges, and the rabbit died within 5 days. *Autopsy:* on opening the abdomen both cecum and large bowel were markedly distended, red and transparent. Lumen filled with bloody mucus. The mucosa shows marked swelling and desquamation. Mucus was positive for diplococcus. Small bowel was hyperemic. There was much mucus in the lumen. Diplococcus positive. Spleen soft. Urine purulent, and the diplococcus was positive. Gall-bladder normal, diplococcus was negative. (See micro-photograph).

*Experiment with rabbit No. 9.* Weight 1 kg. 1 cc. original diplococcus emulsion injected into vein of ear. The rabbit was sick after 3 days with diarrhea and died in 4 days. *Autopsy* not done.

*Experiment with rabbit No. 10.* Weight 2½ kg. 1 cc. original diplococcus emulsion injected into vein of ear after passage through 3 rabbits. Ill in 4 days with diarrhea and died in 10 days. *Autopsy:* large bowel hyperemic. Small bowel for a distance of about 30 cm. was covered with pinhead-sized grayish-white markedly circumscribed elevations.

The remainder of the mucosa was hyperemic. Stomach wall covered with mucus. Mucosa hyperemic. There were abscesses in the liver. Diplococcus was positive.

*Experiment with rabbit No. 11.* Weight 2½ kg. 1 cc. original diplococcus emulsion injected into vein of ear after passage through 4 rabbits. Rabbit was ill after 6 days with diarrhea and died in 10 days. *Autopsy:* part of large bowel mucosa swollen and hyperemic. Lumen was filled with bloody mucus. Diplococcus was positive. Stomach and small bowel mucosa hyperemic. Gall-bladder shows empyema. Diplococcus was positive. Spleen soft. Lungs show evidence of inflammation.

*Experiment with rabbit No. 12.* Weight 1 kg. 1 cc. original diplococcus emulsion injected into vein of ear. There was diarrhea in two days. Feces slimy. The rabbit died in 7 days. *Autopsy:* mucosa of large bowel hyperemic. Much mucus in the lumen. Diplococcus was positive. Mucosa of small bowel hyperemic with area of about 20 cm. long covered with pinhead-sized markedly circumscribed grayish-white elevations. Much mucus in the lumen. Diplococcus positive.

*Experiment with rabbit No. 13.* Weight 2 kg. 1 cc. original diplococcus emulsion injected into the vein of ear. Rabbit became ill in few days. There was diarrhea later, and the animal died in 8 days. *Autopsy:* mucosa of large bowel hyperemic with many punctate hemorrhages. Bloody mucus in the lumen. Diplococcus positive. Small bowel hyperemic, markedly so in small areas. Gall-bladder normal. Diplococcus negative. Spleen was soft.

*Experiment with rabbit No. 14.* Weight 4 kg. 1½ cc. original diplococcus emulsion injected intravenously. The rabbit was ill in one week, later recovered but developed arthritis in 2 joints. After lapse of two months, it died. *Autopsy:* pus found in joint cavities. From one of these diplococcus was cultured. (See micro-photograph).

*Experiment with rabbit No. 15.* Weight 4 kg. 1½ cc. original diplococcus emulsion injected intravenously. Rabbit not ill after 2½ months but arthritis developed in two joints. Pus from these joints was negative for diplococcus. The other organs showed no abnormalities.\*

#### CONTROLS

Experiments were carried out on groups of 4 to 5 rabbits which were chosen from a number of healthy animals.

\*For assistance in the histological examinations, I desire to thank Dr. Behr most heartily.

Those not injected remained perfectly well. Two of them were sacrificed and at autopsy revealed no departure from the normal mucous membrane of the bowel. Other rabbits were injected with diplococcus obtained from the feces of individuals not having ulcerative colitis. These animals also remained perfectly well and the intestinal mucosa showed no abnormalities.

The diplococci isolated from the diseased intestines of the experimental animals proved to have the same characteristics including agglutination properties as the original strain. Histologic examination of the affected intestinal areas was made in a majority of the autopsied animals. Inasmuch as a few rabbits (belonging to one group) appeared to have coccidiosis, it made the histological study of our specimens more difficult. In other rabbits in which no coccidiosis existed, there were very clear-cut departures from the normal mucosa. These consisting at times of swelling and hyperemia, and in other cases of exudation with fibrin and round cell infiltration containing some leukocytes.

Desquamation of the mucosa was present in some cases and in one necrosis was present in the superficial layers. Some of these changes are characteristically shown in the accompanying micro-photographs of rabbit No. 2 and No. 8.

#### SUMMARY OF THE RESULTS

The clinical symptoms displayed by the injected rabbits consisted of rapid loss of weight and in most animals a diarrhea. In nearly all the rabbits after 48 hours the diplococcus was present in the blood stream. After 72 hours, however, they had disappeared. At autopsy marked swelling of the mucosa with a high degree of hyperemia was present. This was particularly true of the large bowel. In the vast majority of cases bloody mucus was seen in the lumen and sometimes in that of the cecum and small bowel. From this material the diplococcus was isolated quite regularly. Histological examinations of the affected tissues have already been mentioned. At times there was empyema of gall-bladder and the culture in these was always positive for diplococcus. Even in those gall-bladders in which the contents showed no macroscopical changes, the diplococci were found. In only one case was there pyuria and it was possible to isolate the diplococci from the contents of this bladder. In all other cases the urine was clear and negative for diplococci. The mucosa of stomach and small bowel frequently was hyperemic. The spleen in nearly all cases was soft and the splenic tissues was positive for diplococci. In one rabbit there was an inflammatory process in the lungs. The other animals, however, showed no abnormal conditions in the respiratory tract. In one case abscesses were found in the liver and pus from these was diplococcus positive. (See table in connection with Author's experiments).

#### CONCLUSIONS

The fact that at autopsy of the experimental animals, the diplococcus was nearly always constantly present in the bloody mucus which covered the swollen hyperemic mucous membranes, and that the histological examination of this structure plainly showed marked pathological changes, leads us to the conclusion that the diplococci intravenously injected have a predilection for the bowel and are able there to initiate a disease process. Even in those rabbits which died or were sacrificed within a few days after the injection

Fig. C. Mucous membrane of colon; rabbit No. 8. Photograph shows rather large mucous fold. Except for a few gland cells the mucosa is thinned and desquamated. In the mucous membrane and to a small degree in the submucosa many inflammatory cells. Marked hyperemia.

---

Fig. D. Diplo-streptococci of Bargen.

---

tion of the diplococcus emulsion and which showed the least pathology, one always found rather wide-spread departures from the normal bowel. The X-ray examinations of the bowel (see section on X-ray) and the examinations of the feces of those patients having the early stages of chronic ulcerative colitis justify the opinion that in these cases, the early stage of the affection is a catarrhal one and ulceration may be expected only in the later stages.

### SYNOPSIS

In a patient who died of ulcerative colitis, the diplococcus of Bargaen was isolated from intestinal ulcers. Material from these ulcers was at once taken and made into an emulsion which after 2 or 3 washings was injected into healthy, normally fed rabbits. In the majority of these rabbits, the clinical picture of enteritis appeared and they died within 5 to 10 days after the injection. From mucus of the intestinal wall particularly of the colon which, as a rule, was bloody, the diplococcus was regularly isolated. The histological examination of these areas of the mucosa revealed marked inflammatory changes.

Control animals remain entirely well. A few which were autopsied revealed normal conditions in the bowel. The diplococcus was never found in these rabbits nor was it present in those animals which were sacrificed for other reasons. The difference between our animal experiments and those of Bargaen and others is likely explained by the fact that the cultures isolated from the ulcers of our patient at operation possessed an unusual virulence. (See Table 1).

The results of our work lead us to the conclusion that the diplococcus is able to develop inflammation of the cecum and colon.

### SUMMARY OF OBSERVATIONS

As has been mentioned, Bargaen originally succeeded in producing colonic lesions in healthy rabbits only with a mixed culture of diplococci and a gram-negative bacilli. Later he was able to produce the same results with pure culture of diplococci, providing the rabbits had been given vitamin poor nourishment. Fridkin and Gray duplicated these experiments of Bargaen in 4 rabbits. At autopsy they found colonic lesions in two of these animals. Gutierrez, Lastra en Blanco could not produce lesions with pure culture of diplococci in rabbits which had been normally fed. They succeeded, however, in producing colonic lesions when they used a mixture of diplococci and anaerobic intestinal organisms. In our opinion these experiments are entirely in line with the first experiments of Bargaen.

Rafsky and Manheim were unable to produce colitis in 4 rabbits which had been fed on a vitamin free diet, with a pure culture of diplococcus. However, other factors such as the variety of the experimental animals and the virulence of the culture may influence the results of the experiments to quite a degree. In our opinion, the results of this work upon only 4 rabbits cannot be considered sufficient argument to question the pathogenicity of the diplococcus. We have succeeded in producing in the laboratory of the Groningen Clinic the same bowel changes in rabbits as the investigators mentioned although in contrast with

their work, we did not use mixed culture but only pure culture of diplococci, and our animals were not given vitamin poor diet but were fed normally.

The question arises why if Bargaen could prove the virulence of the diplococci in rabbits only after they had been placed on a vitamin poor diet for three weeks, were not other investigators successful in their attempts. To this I would give the following answer: The fact that their experiments did not give more positive results points to the possibility that the virulence of these organisms might diminish quite rapidly. It is a well known fact that this is peculiar to many other pathogenic organisms. Rapid isolation and probably extraordinary virulence of our cultures in all likelihood had a favorable influence on the success of our work. These experiments were performed in a very brief period after we succeeded in isolating the diplococci.

### AFTER-TREATMENT

It may still be emphasized that the alleviation of subjective symptoms and the disappearance of pathological elements from the stools do not in any way signify anatomical restoration of the diseased bowel. Rectoscopic and roentgenologic examinations very plainly indicate that this can be expected only after months have elapsed. This is also proven in those cases in which ileostomy and colon irrigations were used. In order to expect continued success from the treatment which has been used, one must exercise the utmost care in the after treatment. This should, leaving active therapy out of consideration, not materially differ from that used in the acute stage of the illness. For those in poor social circumstances, a long stay in a clinic is very desirable.

If the patient comes under the insurance laws, which in our series frequently was the case, the assurance that he will again be able to resume his occupation must be emphasized. Information given to the family doctor generally will take care of difficulties arising in this respect.

Naturally we must not expect, in cases which show marked pathological changes in the colon in which the elasticity may be completely lost, that vaccinations or any conservative therapy will be followed by complete anatomic restoration. In such very advanced cases, we must be satisfied if the case has progressed to a point where the patient's condition is such that his existence will be fairly comfortable. Circumstances, of course, may make it advisable to refer him to the surgeon.

### SUMMARY

During the years 1925 to 1931, Bargaen of the Mayo Clinic at Rochester successfully treated a large number of patients having ulcerative colitis, with autogenous vaccines made from diplococci isolated from the intestinal ulcers found in his cases. On the basis of animal experimentation he considered these organisms the etiological factor in this disease and obtained favorable results by using vaccine therapy.

A number of investigators questioned the pathogenicity of these cocci and therefore did not accept Bargaen's conclusions. There is still much controversy on this question in the literature. One weak point in Bargaen's animal experiments on the pathogenic properties of the cocci was, among others, the fact that before the injection of cocci, the animals had been kept on a vitamin poor diet for 3 weeks.

*Summary of experiments with rabbits injected intravenously with a pure culture of diplococcus:*

It is rather remarkable, as far as we could ascertain from the literature that Barga's vaccine therapy on the whole has been used very little in Europe. It occurred to us rather desirable, therefore, to make further investigations on the subject. Animal experiments were carried out as follows: Pure cultures of diplococci isolated from the ulcers of a typical case of *colitis ulcerosa* which came to autopsy were injected into a number of rabbits which had not been kept on a vitamin poor diet. These injected animals developed diarrhea and at autopsy very distinct pathological

changes were found in the intestinal mucosa. The bloody mucus which generally filled the intestine contained the diplococci in large numbers. These findings placed Barga's contention concerning the pathogenic properties of the diplococci on a firmer basis.

In our investigations X-ray studies of the intestine were very carefully made. Among other things, X-ray films of pathological and non-pathological intestines were compared with the actual anatomical picture. In this way it was made possible to point out pathological deviations which had been formerly overlooked. Regarding the success of the vaccines which were used in the Groningen Clinic (and by some physicians who obtained vaccines from us) it may be remarked that no fewer than 8 out of our 16 patients recovered completely. Six patients were considerably improved and in 2 cases the results were not particularly good. The results therefore justify to a high degree the use of vaccine therapy in cases of ulcerative colitis. Considerable difficulty has also frequently been encountered in the isolation methods used hitherto. We, therefore, adopted a method used by Doctor van der Zoo de Jong which enabled us to obtain pure cultures of these microorganisms in a very easy manner.

#### CASE HISTORIES

**CASE 1.** Mrs. M. V., aged 29, married, entered the Clinic April 22, 1933. Always well until a year ago when she began to have cramp-like pains preceding each bowel movement. No pain during or after defecation. Averaged 3 stools per day; these were mushy and mixed with blood and mucus. Treatment by family physician gave some relief but her pain did not completely disappear. Six months ago there was an increase of blood and mucus in her stools which averaged about 4 per day. Until 7 weeks before entrance there was no change in her condition. She then developed "grippe" and defecated more frequently. Two weeks ago she thought there was some improvement and considered that her stools looked some better. During the past few months there was much fatigue before menstruating. At such times she had much headache. Appetite was good and there was no loss of weight.

**Physical examination:** Patient gives one the impression of being somewhat nervous but otherwise well. Mucous membranes of good color, tongue clean. Papillae not atrophic. She has one carious tooth. Tonsils normal. Pulse normal. Lungs normal. Examination shows a faint systolic murmur over all valve areas, not heard so well after exercise. Abdomen is soft. Parenchymatous organs not felt. No abdominal resistance and no tenderness. Intestinal sounds normal. Rectal mucosa feels thick and the finger when withdrawn is bloody.

**From the notes on April 27:** The first two days no defecations; on the fifth and sixth day there were 3 to 4 daily stools which were large and mushy consisting mostly of blood and mucus. She has continuous abdominal pains which are more intense before defecation.

Feces negative for dysentery. Large numbers of Barga's diplococci present. Blood: H.b. 58 Sahli; erythro. 4,200,000; leuc. 8900. Differential count; baso. ½%; eos. 1%; trans. 10; polys. 55½; small monos. 26; large monos. 7. Sedimentation after 1 hour 50 mm. Wassermann negative.

April 29: Rectoscopy (12 cm.). Mucosa swollen and very hemorrhagic.

May 2: Test meal: Free H.C.L. 37; total acidity 72. No diplococci could be cultured from the stomach contents.

May 3: Barium enema: Lower part of descending colon shows no haustration; contour reveals an irregular saw-toothed appearance.

May 4: No gram-positive diplococci could be cultured from the duodenal bile.

May 6: Three to four defecations daily; much bloody mucus mixed with the feces.

May 9: Vaccine therapy begun. She was given high caloric diet. No coarse food stuffs allowed.

May 11: Defecates 4 times daily mostly blood and mucus.

May 19: One to two movements daily consisting of blood, mucus and feces. Occasionally less blood and mucus.

May 19, 20, 21: Pre-menstrual temperature rise up to 38.5° C.

May 24: Blood: H.b. 54 Sahli. Two defecations daily; less blood and mucus than on entrance. Some parts of stools show no blood or mucus.

June 24: She feels very much better, wants to sit up. Stools thick and mushy but still contain some blood and mucus. Sensitization tests, (Storm van Leeuwen) intracutaneous; human skin, moulds, mites and horse, weakly positive.

June 20: Feces thick and soupy, some portions show no blood or mucus to the naked eye.

June 23, X-RAY EXAMINATION: After introducing air in the colon, the renal flexure and descending colon revealed a granular aspect.

From the time that the vaccine was given in quantities of 0.8 cc. the patient reacted with a temperature increase up to 38° C, sometimes to 38½° C at which time she feels ill and has headache. Between injections her temperature ranges around 37 C.

June 28: Bowels move once or twice daily. Feces now show normal formation. Macroscopically no blood or mucus. Microscopically particles of mucus.

July 4: Stools normal. No marked temperature rise after vaccination.

July 11: She feels well. Carious tooth extracted. Bowels move daily. Stools are normal and contain no pathological substances. Temperature in the intervals between vaccinations averages 37.5 C. After vaccinations this rises 0.3° to 0.4° C. Blood: H.b. 62 Sahli. She was dismissed. The same therapy to be continued by family doctor. Was given Bland's pills for anemia.

August 15: (Report): Doing her housework but this brings on fatigue. The feces are normal with no blood and mucus. Vaccine discontinued.

August 29: Still fatigued after work. Feces macroscopically normal. Microscopically mucus. Blood: H.b. 72 Sahli. Sedimentation test after 1 hour 14 mm.

X-RAY ("umbrathor"): Contrast mass reaches the small bowel. Descending colon shows only little haustration. Mucosa of hepatic flexure shows some evidence of intestinal folding but the transverse and descending colon none. Mucous membrane appears swollen. Patient is advised to stop all housework.

December 26: Because of social conditions, patient has been obliged to do much work. For a couple of weeks, again has thick mushy stools with blood and mucus, about 2 to 3 per day. Has more pain. Absolute rest ordered. Vaccinations again prescribed.

February 28, 1934: Condition the same as in December. Has been unable to rest. Family doctor was written about her condition. Vaccinations stopped. Blood: H.b. 62 Sahli. Was given 1 gram *ferrum reductum* 3 times per day.

April 20: She has rested since March, general condition much better. Defecates 2 or 3 times per day. Stools thick and mushy, some blood and mucus. Still has abdominal pain before each stool. Blood: H.b. 68 Sahli; leuc. 9000; differential count, eos. 1; trans. 7; polys. 58; small monos. 29; large monos. 5.

Results of vaccinations: Rapid improvement at first so that in 9 weeks the subjective complaints disappeared and the feces showed no more pathological elements. However, after about 4 months her condition grew worse which, in our opinion, must be attributed to the unsatisfactory after treatment.

CASE 2. Mr. J. B., aged 15, student in a technical school admitted to the medical clinic January 15, 1933. He was suddenly taken ill in November, 1932, with diarrhea, averaging 10 thin watery stools per day. Each defecation was preceded by severe pain in lower abdomen. During the defecation and afterwards there was no pain. Feces showed blood and mucus. He never vomited. Does not know whether or not he had fever. He remained in bed the first 4 days of his illness, then got up. Appetite at this time fairly good. No other illness of this type in his community. The family doctor prescribed different remedies without any relief. Gradually condition improved. Frequently of bowel movements was lessened. Stools gradually changed from watery to mushy and abdominal pain which preceded defecation improved and finally ceased. One week before admittance, he was having an average of one daily stool which was thick and soupy, occasionally fairly well formed but still contained some mucus and had a very disagreeable odor. There has been no perceptible loss of weight. He had measles and whooping cough in childhood, also tonsillotomy.

From the notes: He is of normal build and gives one the impression of not being ill. Pulse normal, mucous membranes good color. Tongue is moist, not coated. No atrophic papillae. Teeth are sound. Tonsils are normal. Heart and lungs normal. Liver and spleen not palpable. Intestinal loops not felt. No abdominal tenderness. No excessive abdominal noises. Rectal mucosa feels normal. Examining finger shows no blood.

January 23: Bowels move 2 or 3 times daily. Stools normal in color, shape and consistency. No occult blood. Microscopically there is some mucus. Bacteriological examination negative for dysentery.

January 26: Rectoscopy is negative.

January 27: Examination of fractional meal, 5 4; 2 8; 6 12; 16 22; 10 21; 15 25; 22 32; 24 36; 35 50.

January 28: Roentgen photos after injection of air. Hepatic flexure reveals granular aspect.

February 10: Stools now number only one per day. Microscopically mucus. Rectal temperature never over 37.6° C.

February 12: Dismissed.

April 4: (Report): Developed diarrhea one or two weeks after dismissal. Abdomen not tender. Rectal examination negative. Feces to be sent.

April 15: Feces mushy, much bloody mucus and very offensive odor. Microscopically nothing new. Negative for dysentery. Diplococcus of Bagen present in large numbers. Vaccine prepared.

April 29: Still has frequent abdominal pain. Defecates 4 times a day. Stools thin and mushy, much mucus and very disagreeable odor.

Blood: H.b. 76 Sahli; erythro. 5,200,000; leuc. 7,000; differential, baso. ½; eos. 1½; trans. 8; polys. 62; small monos. 20; large monos. 8. Sedimentation after 1 hour 30 mm.

First injection of autogenous vaccine administered. Vaccine to be continued by family physician. General diet but no coarse food stuffs.

January 13: (Report): At first condition unchanged but later there was improvement. The abdominal pains disappeared, stools became firmer in consistency and occasionally were normal. Some blood and mucus at times.

X-ray films of bowel: Hepatic flexure and transverse colon reveal much swelling of mucous membrane. Upper descending colon reveals only transverse folding.

July 11: (Report): Original condition about as it was on June 13. One week ago stools again became thin and more numerous, preceded by abdominal cramps. Feces thick and mushy. No macroscopic mucus. Microscopically mucus is present.

August 8: (Report): No complaints. Bowels move daily. Normally formed stools, negative to naked eye. Laboratory reports no pathological elements. Blood: H.b.

80 Sahli. Sedimentation after 1 hour 8 mm. Vaccination discontinued.

October 5: (Report): No complaints, has daily stools, normally formed. Negative for diplococcus of Bergen.

December 15: He has been entirely well; stools remain normal.

March 20, 1934: Feels entirely well. Stools normal.

*Final comments on vaccinations:* After about 12 weeks all subjective complaints have disappeared, stools were normal and contained no pathological elements. His condition has remained satisfactory up-to-date.

CASE 3. Mr. J. P., aged 45, factory worker, admitted to the surgical clinic December 30, 1930, with following complaints: For the past year he has had continual pain in lower abdomen which became worse just before defecation and persisted during the bowel movement. At first stools contained some blood, later also mucus and pus. He had frequent urge to defecate. Several times a day a fairly large quantity of blood, mucus and pus was expelled. He frequently had painful rumbling in his abdomen which improved after passing flatus. During the preceding few months before admittance there was some improvement in his condition.

*From the notes:* Generalized tenderness over left lower abdomen. Rectal palpation is somewhat painful but reveals no special findings. Examining finger is bloody.

*Rectoscopy* (15 cm.): Intestinal wall at this distance from the anus is covered with mucus. After removal of this, the mucosa looks markedly hyperemic.

January 8, 1931: Persistent blood in the stools.

January 9: X-ray examination confirmed the diagnosis of ulcerative colitis. The process is localized in the lower part of descending colon and in the sigmoid.

January 20: *Appendicostomy* is done. For first few days post-operative, the colon was irrigated with weak tea once a day.

January 29: About 1 cm. of the protruding appendix has become necrotic. This was removed and a drain attached to the stump.

March 2: No complaints. The fistula functions well. Temperature normal. Bowels move daily. Feces still show blood.

March 14: Stools not yet entirely formed, reddish brown in color and still contain occult blood.

March 31: Occasionally stools are negative for blood.

April 8: Drain removed.

April 11: Rectoscopy revealed no blood or mucus. Mucous membrane looks velvety. Patient dismissed.

May 12, 1931: (At the Poliklinik): Patient has regular daily stools, no blood or mucus in feces. Still has fistula resulting from appendicostomy. This shows very little discharge.

July 13: Patient has developed hernia in operation scar. This still discharges. He is about to resume his work.

October 13: Patient has daily normal stool, negative for blood and mucus.

*Rectoscopy:* The lower 10 cm. of the mucosa looks normal, above that it is a little swollen and there is much mucus attached to it. No bleeding or ulcers observed.

December 10: No complaints: Bowels move regularly and stools are normal.

*Rectoscopy* (15 cm.): Mucous membrane still looks velvety.

March 16, 1932: The operative scar shows a small hernia with a bit of granulation tissue protruding. Patient is doing his work.

May 3, 1932: Stools again contain much blood.

*Rectoscopy:* Rectal mucosa bleeds slightly. Patient referred to medical department for vaccine treatments.

May 24: Patient admitted to medical department. Since May 3 the stools have gradually become more bloody. Abdominal pain before and during defecation. Otherwise

patient feels fairly well, is not unduly fatigued and has good appetite. No loss of weight.

*From the notes:* Gives the impression of being well. Tongue slightly coated; no atrophic papillae. Teeth are well taken care of. No caries. Tonsils apparently negative. Heart and lungs normal. In the lower right quadrant, there is an oblique operation scar about 10 cm. long. On the left, can be felt a somewhat tender loop of gut running vertically and about the thickness of one inch. In this vicinity, one frequently can hear intestinal rumbling. The right testicle is enlarged and tender.

*Rectal examination:* The rectal mucosa feels thick. Slight pressure with finger elicits pain. Examining finger shows blood on withdrawal.

May 27: Defecates once or twice daily. Stools show largely blood, mucus and pus. Inasmuch as the patient feels constipated, a soap suds enema was given. This brings some hard fecal masses. During the day on several occasions, rather purulent matter was excreted.

*Examination of stomach contents 45 minutes after test meal:* No free HCL, total acidity 38. No pepsin, no lactic acid. Stomach contents reveal no gram-positive diplococci.

*Blood:* H.b. 68 Sahli; erythro. 4,200,000; leuc. 8,200; differential, immature cells 1%; trans. 14; polys. 64; small monos. 18; large monos. 3. Sedimentation test after 1 hour 48 mm. Wassermann negative.

June 1: During last few days defecates twice daily. Stools a mushy mass consisting of mucus, blood and particularly pus. Some portions contain hard masses of feces. Examination of stool was negative for dysentery but revealed large numbers of Bergen's diplococci. Autogenous vaccine made. Rectoscopy (12 cm.) revealed a bloody swollen mucosa.

June 2: *X-ray films* ("umbrathor"): Sigmoid colon rather stiff; haustration practically absent. Mucosal shadow reveals only coarse transverse folding in the distal part of the transverse colon. The sigmoid shows irregular mucosal fold formation. No longitudinal folds.

June 6: Autogenous vaccinations begun. Patient was given acidol-pepsin, vitamin rich diet but no milk. Coarse foods and substances leaving much residue not allowed.

June 13: Sensitization reactions (Storm van Leeuwen) cutaneous, positive for cat. Intra-cutaneous weakly positive, for human skin.

Daily stools for the last few days consisted of a rather purulent mass mixed with some solid portions of feces. Inasmuch as patient complained of feeling rather "full" he was given an occasional enema of warm water which generally brought much pus mixed with some solid stool. This treatment gives much relief.

June 17: Daily stools of thin, mushy character containing pus with a couple of hard balls of fecal matter.

June 26: Occasionally no daily stools, necessitating a warm water enema. Patient is given castor oil to regulate his bowels.

July 1: *X-ray films* ("umbrathor"): After filling, the descending colon and sigmoid colon show little haustration. After emptying, the sigmoid is found to be narrow and shows only irregular coarse transverse folds. In the sigmoid and descending colon ulcer shadows are seen and the submucosa is undermined. After introducing air, the sigmoid, descending colon and renal flexure gives the picture of a braided band.

July 7: Castor oil continually causes nausea so liquid paraffin is substituted.

July 17: The stools are thin, mushy and dark brown. Macroscopically negative. Microscopically leucocytes.

*Rectoscopy* (18 cm.): Mucosa below plica recto-sigmoidale looks normal, but above this point is still somewhat red and swollen.

July 23: *Blood:* H.b. 74 Sahli; erythro. 4,475,000; leuc. 7900; differential, trans. 10½; polys. 65; small monos. 20; large monos. 4½; sedimentation after 1 hour 34 mm.

Feces rather more thick and mushy. Microscopically no leucocytes. Patient going home to continue present treatment.

*Poliklinik report:* August 4, 1933: During first few days at home there was again some blood in the stools; however, the feces soon became formed and brown in color while blood, mucus and pus were no longer observed. Sedimentation after 1 hour 30 mm.

August 17: Regular daily defecations. Feces are formed and no blood, mucus or pus could be seen. Microscopic examination negative.

*X-ray films ("umbrathor"):* After filling, the renal flexure, descending colon and sigmoid reveal fairly good haustration. Mucosa shows normal transverse foldings. The sigmoid and descending colon again reveal some longitudinal folding. Introduction of air reveals a coarse granular appearance in the renal flexure and a portion of the transverse colon.

Vaccine treatment omitted. Patient to continue with his diet. Also hydrochloric acid and pepsin.

October 20: No complaints. Patient has normal daily defecation.

*X-ray films ("umbrathor"):* Ulcers have disappeared, normal intestinal folding.

*Rectoscopy:* Normal mucosa. Sedimentation test after 1 hour 18 mm.

December 1: Condition same as October 20. Revaccinations begun. To continue for 3 weeks. Resumed his work January 15, 1934.

*X-ray films* show colon negative.

April 24, 1934: No complaints. Sedimentation test after 1 hour 16 mm.

*Final comments on vaccinations:* Success of vaccinations. In about 10 weeks subjective complaints have disappeared. Feces are then normal in consistency and contain no pathological elements. After 4½ months on the basis of X-ray, and rectoscopic examinations, we consider the intestine apparently restored to normal.

CASE 4. Mr. B. P., aged 15, farm laborer admitted to medical clinic July 22, 1933. In December, 1932, he was suddenly taken with severe diarrhea averaging 7 to 8 stools during the day and also several times at night. He felt sick and tired and had diffuse abdominal pain and cramps before each defecation. Even after his bowels moved there was often marked tenesmus. Much rumbling in abdomen. He continued to do his work but complaints up-to-date have remained about the same although rather less severe. The stools have gradually changed from watery to thin soupy and finally to a thick mushy consistency; frequency about 4 times per day. At first his distress was largely at night but lately more during the day. His appetite is good, and he knows of no special food substances which increase his distress.

*Case notes:* The patient is long and of asthenic type. Pulse slightly arrhythmic (respiratory). Tongue normal. Papilla not atrophic. Teeth negative. Heart and lungs normal. Abdominal pressure causes rumbling. In the region of cecum, there is felt a rather smooth resistance, probably intestinal coils. The sigmoid colon can be felt as a smooth linear structure.

*Rectal examination:* Mucosa feels normal, examining finger brings no blood or mucus. Rectoscopy negative. Stools show mucus but no other pathological elements.

*Blood:* H.b. 80 Sahli; erythro. 4,840,000; leuc. 6800; eosin. 7; baso. 1; trans. 5; poly. 52; small monos. 31; large monos. 4; sedimentation after 1 hour 1½ mm.

July 28: Bowel movement sluggish, occasionally necessitating a warm water enema. Stools thick and mushy, much mucus, no blood.

*Stomach contents:* 45 minutes after test meal: H.C.L. 52; total acidity 72. Microscopically nothing remarkable. Culture for diplococcus of Bargaen, negative.

August 2: *X-ray films ("umbrathor"):* On filling descending colon only slight haustration observed. Mucosa of the upper part of descending colon markedly swollen. After introducing air in sigmoid and descending colon a spotty and marbled appearance is observed.

August 5: Defecates once daily. Stools thick and mushy. Much mucus. Negative for dysentery. Positive Bargaen's diplococcus.

August 10: Duodenal drainage. B-bile negative for Bargaen's diplococcus. A-bile, lipase normal. Trypsin normal.

Rectoscopic examination shows no ulcers. From material obtained from the intestinal wall, cultures were made for vaccine.

August 18: Continual abdominal pain and distressing sensation in abdomen, cramps before defecations. Bowels move once or twice daily. Stools are thick and mushy containing much mucus. Autovaccinations begun.

September 7: Condition the same as August 18. Dismissed. Vaccinations to be carried out at home.

September 22: Stools thick and mushy containing much mucus.

*Blood examination:* Sedimentation after 1 hour 8 mm. H.b. 83, Sahli; leuc. 7300; eosin. 4; trans. 5; poly. 62; small monos. 24; large monos. 5.

October 28: Abdominal pain much less; feces the same as on previous examinations.

December 1: Subjective complaints are disappearing. Defecates once or twice daily. Feces thick and mushy with decrease in amount of mucus.

January 3, 1934: Practically no more complaints. Stools normal.

January 28: Patient feels that he has recovered. Stools normal and formed, containing no pathological elements.

March 11: Condition as in last report.

*Blood:* eosin. 4; trans. 4; poly. 66; small monos. 24; large monos. 2. Sedimentation after 1 hour 6 to 8 mm.

*Final comment:* After 3½ months very marked improvement observed in both subjective complaints and consistency of stools. After 5 months complete recovery.

CASE 5. Mrs. K. Z., 36, married, first admittance to the clinic February 17, 1930. During 8 months while pregnant had continuous vomiting and severe diarrhea. No abdominal pain. On January 4 was delivered of a six months dead fetus. After parturition there was some improvement, but then renewed vomiting associated with pain and rumbling in abdomen. The rumbling seemed to relieve the pain. Later, diarrhea sometimes averaging 10 movements per day of thin stools, frequently mixed with blood. Appetite good. Micturition normal.

After January 4 did not menstruate. Formerly menstruations were regular.

Most important notes: At first vomiting but not after February 20. Defecated 4 to 6 times per day, no blood. After Schmidt's test meal, stools showed many muscle fibers and much neutral fat. Forty-five minutes after test meal no free HCL.

*X-ray examination of stomach* not remarkable.

March 6: Patient was given HCL dilute and "enzypan" tablets.

March : "Pancreon" substituted for "enzypan."

March 18 to 20: Patient given an apple diet according to Moro.

March 20 to 22: General diet with limitation of fluids.

March 29: No more diarrhea. Dismissed. To continue HCL and "pancreon."

Report April 25: Occasional diarrhea. Along with medication mentioned, a generous fruit and vegetable diet prescribed.

September 2, 1931: Was readmitted. After last report developed continuous diarrhea, otherwise no complaints. About a month ago suddenly without known cause, the diarrhea became worse and severe vomiting developed.

sometimes 10 times per day. Stools often contain mucus, sometimes blood, and have disagreeable foetor. Diffuse abdominal pain in upper abdomen. Defecation not painful; loss of weight 18 Kg.

*From the notes:* Diarrhea 3 to 5 times daily. Feces bloody. Vomits about 4 times a day.

*Blood:* H.b. 80 Sahli; erythro. 5,230,000; leuc. 17,000; differential; immature cells 1; trans. 55; polys. 21; small monos. 18; large monos. 5.

October 1 to 3: HCl and pepsin plus apple diet, according to Moro. Vomiting nearly everything.

October 3: Soft diet.

October 5: Still vomiting and diarrhea. Papaverine 20 mgr. 3 times daily prescribed.

October 13: No more vomiting or diarrhea.

October 24: Papaverine discontinued.

October 30: Dismissed in good condition.

April 14, 1933: Readmitted. Four weeks ago an attack of "grippe" initiated another abdominal attack which was characterized by pain, rumbling and severe diarrhea, about 10 times daily with cramps preceding defecation. Feces watery with much mucus and blood. Frequent vomiting. Up-to-date this condition has persisted. Examination of abdomen shows no tenderness. No intestinal loops palpable.

Rectal examination not remarkable except for some mucus on examining finger.

Rectoscopy (12 cm.): Rectal mucosa thickened and bloody.

*From the notes:* Temperature up to 39° C. Nearly all food vomited. Defecations 4 to 5 times daily, feces thin, slimy and bloody with marked foetor. No neutral fat, starch or muscle fibers. Negative for dysentery but positive for Bagen's diplococcus in almost pure culture. Auto-vaccines prepared.

*X-ray (Barium Meal):* Colon shows up like stiff tube with contour as it were "eaten out." Test meal after 45 minutes: no HCl; total acidity 36; no pepsin; negative for Bagen's diplococcus.

*Blood:* H.b. 72 Sahli; erythro. 3,680,000; leuc. 8300; differential; immature cells 5; trans. 25½; polys. 47; small monos. 17½; large monos. 5. Leucocytes show toxic granulation. Red cells not remarkable. Sedimentation after 1 hour 23 mm.

April 20: Vaccine therapy begun. Was given acidol-pepsin and soft diet.

May 3: Condition improved, temperature running to 37.7° C. Defecation once a day. Feces thin, soupy with a little mucus and blood. Occasional vomiting.

May 8: Defecations once in two days. Feces formed normally. Still show blood and mucus.

May 13: General condition excellent. No more vomiting. During the past few days, defecation once in 3 days. Stools normal in form. Still some blood and mucus. Sedimentation after 1 hour 10 mm.

May 28: Temperature normal. Defecates once a day. Feces normally formed. No macroscopic blood or mucus. Microscopic mucus.

*Blood:* Trans. 9; polys. 63; small monos. 23; large monos. 5; no toxic granulation, red cells not remarkable.

June 24: No complaints. Defecates daily. Macroscopically no blood or mucus.

July 20: Microscopically feces show no pathological elements.

March 14, 1934: Feels entirely well, bowels move daily, feces normal. Sedimentation after 1 hour 4 mm.

*X-ray films ("umbra"):* Transverse colon shows normal haustration, remainder of the film also normal.

*Final comments on vaccinations:* After 6 weeks patient feels very well. Feces are normal in consistency and contain no pathological elements. After 11 months X-ray films appear entirely normal.

CASE 6. J. G., aged 38, married, traveling salesman; about 7 years ago, he first noticed a mucus discharge with his formed stools. At this time he developed a rather scaly condition of the skin of the extensor surface of the lower arm and the flexor surface of the right lower leg (neuro-dermatosis). There was a gradual increase in the amount of mucus excreted. Bowel movements increased to an average of twice daily and the consistency of the stools became softer. For four years has had hay fever which was relieved by treatments of pollen extract administered by Professor Benjamins.

During the last two years his intestinal condition has grown worse and the defecation frequently was preceded by a passage of mucus. Stools gradually became softer with increased frequency, averaging of late 5 to 7 daily and sometimes consisting only of mucus. Defecation was not painful neither was it preceded by any distress.

*From the notes:* A healthy looking man; mucous membranes of good color. Tongue slightly coated. Papillae not atrophic. Tonsils not enlarged. Teeth show some defects and some caries. Lungs and heart normal. Abdomen not distended. No visible peristalsis. No particular resistance to abdominal palpation. No tenderness. Parenchymatous organs not felt. Many intestinal sounds heard in the region of colon.

*Rectal examination:* Rectal mucosa feels normal. Examining finger shows no blood.

*Blood examination:* H.b. 71 Sahli; erythro. 4,100,000; leuc. 6500; differential, eos. 3; trans. 8; polys. 54; small monos. 29½; large monos. 5½. Sedimentation after 1 hour 35 mm.

November 15: *Sensitization reactions:* Cutaneous tests strongly positive for rye pollen. Defecates 3 to 4 times daily. Feces thin and mushy with shreds of mucus. Microscopically no connective tissue, no fat, no starch. Patient declares that the diarrhea is unfavorably influenced by activity.

November 20: Continued activity has resulted in more frequent defecations, from 5 to 8 times daily. Stools are thinner and there is diffuse abdominal pain but no tenesmus.

November 22: Forty-five minutes after test meal: No free HCl; total acid 16; no pepsin. Sedimentation not remarkable.

November 24: *Rectoscopy* (from 12 to 25 cm.): Mucosa bloody and swollen but no ulceration.

November 25: *X-ray film* (Barium enema): After introduction of air, a spotted and marbled appearance noted.

November 26: Given 2 cc. "campolon" twice a day; also acidol-pepsin and soft, high vitamin diet.

December 9: Defecates once daily. Stools formed but microscopically show mucus.

January 2, 1933: Instead of daily administration of "campolon" and "ventraemon," 100 grams of liver was given daily and every other day 2 cc. "campolon."

January 6, 1933: Defecates 3 to 5 times a day. Stools again thin and mushy containing much mucus, "campolon" 2 cc. twice daily and "ventraemon" 20 grains twice daily.

January 30, weak: Temperature rises daily to 38.5° C. Defecates about 8 times daily, stools are thin with mucus and blood. Patient has lost 7 kg. in last few weeks. He was given clysmata of "dermatol."

February 10: Condition serious. Daily temperature runs to 39.2° C. Defecates 10 times per day. Negative for dysentery but shows almost pure culture of Bagen's diplococcus. Vaccine prepared. Was given laudanum.

February 18: *Blood:* H.b. 46 Sahli; erythro. 3,010,000; leuc. 7300; differential; immature cells 4; trans. 28; polys. 29; small monos. 35; large monos. 4. Leucocytes show toxic granulation. Red cells not remarkable. General

condition somewhat better. Defecates 4 times per day. Thin mushy stools, much blood and mucus. Temperature up to 38 C. Autovaccinations begun.

March 2: Duodenal drainage for A-bile and B-bile. From B-bile no Barga's diplococci can be cultured. Normal ferments present in A-bile.

March 9: H.b. 43 Sahli; differential, eos. 2; immature cells 2; trans. 5; polys. 28; small monos. 40; large monos. 3. Slight toxic granulation. Red cells not remarkable.

March 27: General condition much improved. Defecates 3 times per day, feces thin and mushy. Macroscopically no blood or mucus. Microscopically mucus. Temperature running up to 37 C. "Ventremon" 3 times daily 20 grams. Given "arsylen" tablets.

April 3: Has gained 3.4 kg. in past 2 weeks. Blood: H.b. 43 Sahli; differential; baso. 1; immature cells 1; trans. 14; polys. 41; small monos. 38; large monos. 5. Weight shows steady increase averaging 2 kg. a week. Temperature 37° C. Defecates twice daily, stools are formed, there is no blood or mucus. One gram of *ferrum reductum* is given 3 times a day.

May 18: Blood: H.b. 57 Sahli; sedimentation after 1 hour 21 mm. Dismissed. Vaccination therapy discontinued.

June 20: To continue with *ferrum reductum*. Defecates once or twice daily. Stools well formed, no blood or mucus.

Blood: H.b. 67 Sahli; sedimentation after 1 hour 38 mm.

July 21: General condition excellent. Blood: H.b. 76 Sahli. Sedimentation after 1 hour 8 mm.

August 20: About to resume his work.

August 28: Both knee joints markedly swollen. Free fluid demonstrable. Defecates twice a day. No blood or mucus.

September 9, 1933: Entered surgical department with very painful and swollen knee and ankle joints. Examination of joints difficult because of severe pain. The skin above the swollen areas is warmer than that over the joints. Puncture of the right knee joint brings a clear, rather opalescent, light yellow fluid which is sterile and contains mostly leucocytes. Defecates twice daily.

Stools thick and mushy, no blood or mucus.

September 23: Blood transfusion 400 cc., "campolon" 2 cc. every other day. Defecates 8 or 10 times per day. Stools thin and mushy with mucus.

October 5: Blood transfusion.

October 17: Clysmata of "rivanol" 1 to 1000. Defecates 7 times a day.

October 26: Irrigations discontinued. Defecates 13 times a day. Stools thin and mushy with mucus and blood. Referred to medical department.

October 30: Readmitted to medical department. Temperature 38.5° C. General condition poor. Defecates 25 times a day, stools consist of thin, slimy, bloody material. Weight 56 kg. (May 18, 72 kg.). Temperature 38.6° C.

Therapy: Takes only a couple of zwiebach and fluid in the form of weak tea. Laudanum and acidol-pepsin given.

Blood: H.b. 52 Sahli; erythro. 3,620,000; leuc. 6500; differential; baso. 1; eos. 1; trans. 12; polys. 29; small monos. 45; large monos. 12. Sedimentation after 1 hour 35 mm.

November 3: Defecates 15 times daily. Stools contain slimy bloody material, also Barga's diplococcus. Dysentery negative. Tubercle bacilli negative.

Diet: Toasted bread, soup, zwiebach, potato puree, banana, orange juice.

Rectoscopy: (12 cm.): Mucosa bloody and swollen.

November 12: Temperature 37.8° C. Autovaccines begun. Laudanum dosage gradually decreased. Given "idosan." Knee joints now only slightly tender on palpation.

December 12: Rectoscopy (15 cm.): Mucosa bloody and swollen.

X-ray films ("umbrathor"): Colon shows nodular hyperplastic stage of ulcerative colitis.

September 16: Blood: H.b. 55 Sahli. *Ferrum reductum* 3 grams daily. Feces show no blood or mucus macroscopically. Weight 60 kg.

December 31: Defecates 6 times daily, feces thin and mushy, no blood or mucus.

Blood: H.b. 75 Sahli.

February 22: Knee joints normal.

X-ray films ("umbrathor"): Nodular stage of ulcerative colitis or pseudopolypsis (?). Vaccination discontinued. Direct sunlight advised.

April 10: Patient feels that he has recovered. Light work allowed on his urgent request. Defecates twice daily. Stools normally formed, no pathological elements. Sedimentation after 1 hour 20 mm.

Final comments on vaccinations: After 10 weeks all subjective symptoms have disappeared and no more pathological elements found in stools. A few months later an acute arthritis developed. Most likely psychic factors were instrumental in causing an acute exacerbation of colitis. Revaccination brings recovery.

CASE 7. N. N., aged 30, high school teacher, married. In the summer of 1926 he first noticed blood in the stool and tenesmus. Rectoscopy revealed ulcers in the sigmoid colon. Enemas of silver nitrate solution brought improvement.

March 22, 1927: Admitted to the medical clinic. Maximum temperature 37.3° C. Stools negative for dysentery. Negative for tubercle bacilli. Treatment 30 mgr. of emetine daily, subcutaneously.

April 11: Emetine discontinued. Is getting clysmata of silver nitrate solution 2%.

April 28: Silver nitrate discontinued and 1/2% "dermatol" irrigations substituted.

May 2: "Trannalbin" 0.5 grams twice daily.

June 27: Clysmata of "dermatol" and "tannalbin" discontinued. Was given bacteriophage 1 cc. every 5 days. Cleansing enema in the morning.

July 13: Last dose of bacteriophage given. Last injection caused no temperature rise.

July 23: Stools thick and mushy, occasionally blood and mucus. Dismissed. Soon after dismissal there was more frequency of defecation with thin, bloody mucus stools.

August 28: Defecated 5 times a day. Much blood. Temperature up to 40° C.

September 28, 1928: Readmitted to medical clinic at Groningen. X-ray of descending colon shows pseudo-polypsis. Blood: Leuc. 6900; differential, eos. 3; trans. 19; polys. 36; small monos. 36; large monos. 6. Clysmata of tannin solution. Low residue diet. Later fresh vegetables.

January 7, 1929: Tannalbin 3 times daily 0.5 grams.

January 16, 1929: Rectoscopy: Mucosa atrophic. "Dermatol" clysmata. Blood gradually disappearing from feces although these remain frequent and thin. Resumed his occupation in May. After a few days, stools again become bloody.

May 10, 1929: Readmitted to medical clinic. Diet: bananas, oranges, figs, grapes and yogurt.

May 16: Clysmata of 3% hydrogen peroxide and tannalbin solution.

May 19: Clysmata discontinued: Given 50 grams of liver per day, also raw vegetables, direct sunlight and *bolus alba*. Defecates 5 to 8 times daily, much blood and mucus. Temperature up to 38.5° C. Clysmata of 300 cc. water containing 2 cc. adrenalin and 1% yaten.

May 31, 1929: Because of poor condition, transferred to surgical division.

June 7: Rectoscopy: Severe inflammatory condition. Polyp removed.

June 13: Appendicostomy: Irrigations with camomile tea. Kelling's diet.

June 27: Feels much better, much less pain but still blood and mucus.

July 10: Defecates once or twice daily. Returned to medical department. Much blood and mucus in the stools. Irrigations of camomile tea discontinued and clysmata of "rivanol," tannin and "dermatol" substituted. Change in medication always seems to bring about slight improvement which, however, is not permanent. The patient seems to feel that his psychic attitude has a great influence on his intestinal condition.

August 30: Condition improved to such extent that he is able to resume his work. Again recurrence of blood in two weeks and condition gradually growing worse.

September 14: Marked proctitis. Rectal wall inflamed with purulent material attached to mucosa for a distance of 22 cm. Bergen's diplococcus not found.

September 21: Diplococcus present. Vaccine prepared.

September 28: Autovaccinations begun. This treatment resulted in improvement.

March 21, 1931: Feels exceedingly well. Blood: H.b. 72 Sahli. Rectoscopy shows no abnormalities. Defecates once daily. Feces formed, no mucus or blood.

June 31: Again vaccinated, 10 injections given.

April 5, 1933: Was asked to come for examination. Patient has done his work for 2½ years without any complaints. No abnormal symptoms. Feces are thick and formed in part. Microscopically no pathological elements.

May of 1933: Sudden exacerbation of 10 defecations daily with tenesmus. Stools slimy and bloody, Bergen's diplococcus found. Autovaccinations for 8 weeks results in gradual recovery. Patient, however, went back to work too soon and his condition again becomes worse.

January 24, 1934: Readmitted to medical clinic. The sigmoid colon can be felt as a linear tube which is painful to palpation. Rectal examination: Mucosa feels rough and examining finger shows blood and mucus.

*Rectoscopy:* Mucous membrane swollen. Defecates 5 to 8 times daily. Feces show blood and moderate amount of mucus. Negative for dysentery. Positive for Bergen's diplococcus. At first the treatment consisted only in the use of a diet poor in residue and magnesium sulphate in the morning because of a continuous obstipation.

*Blood:* H.b. 75 Sahli; erythro. 5,100,000; leuc. 6800; differential; eos. 2; trans. 7; polys. 44; small monos. 43; large monos. 4. Sedimentation after 1 hour 10 mm. Wassermann negative. Forty-five minutes after test meal: Free acid 31; total acid 60; no diplococci in stomach contents.

February 9: Condition somewhat easier. Defecates two to three times a day. Stools thick and mushy, some portions consisting of blood and mucus.

*X-ray films* ("umbrathor"): Descending colon reveals pseudo-polyposis. Remainder of gut gives a normal shadow.

February 20: General condition as of February 9: *Blood:* Differential eos. 2; trans. 3; polys. 44; small monos. 48; large monos. 3. Sedimentation after 1 hour 8 mm. Autovaccinations begun.

March 20: Defecates once daily. Stools sometimes normal, sometimes thick and mushy. No blood or mucus.

March 30: Dismissal. No complaints. Vaccinations discontinued. Is to remain at rest for some time.

April 25: No complaints. Defecates once daily. Stools sometimes mushy, sometimes formed. No blood or mucus.

*Final comments on vaccinations:* In this extreme case in which pseudopolyposis had developed, complete clinical cure followed autovaccinations. Nevertheless, after 2½ years there was a recurrence which again was followed by recovery after autovaccination. The final results in this case, however, cannot be definitely foretold.

CASE 8. K. Z., a seaman, aged 64, married, admitted April 27, 1932, to the surgical clinic. For about 10 years for periods of several months had much blood and mucus in the stools but at intervals these again were normal. Four weeks before admission patient developed sudden diarrhea, about 6 times daily. Feces containing blood and mucus. Tenesmus. Feels tired and very much exhausted.

*From the notes:* Gives the impression of being healthy. Mucous membrane pale. Teeth carious and defective. Heart and lungs normal.

*Abdominal examination:* In the lower left quadrant the sigmoid colon can be felt like a band; otherwise nothing remarkable.

*Rectoscopy:* (22 cm.): Mucosa hyperemic with small hemorrhagic areas, but no ulcers. Feces contain much blood.

*Blood:* H.b. 50 Sahli; erythro. 3,830,000; leuc. 7800. Was given clysmata of rivanol 1 to 5000 twice daily.

May 23 and June 12 blood transfusions.

July 8: Rectoscopy: Mucosa bloody. Was dismissed. Family physician to continue administrations of "rivanol" clysmata.

Report October 7: Few complaints. Given daily clysmata of "rivanol" solution.

Report November 4: Condition much improved, clysmata discontinued.

March 8, 1933: Some red blood in the stools. Sent to medical department for vaccine therapy.

March 13, 1933: Medical department Poliklinik. Not so well of late. Complains particularly about stiffness in the joints. More blood in the stools than formerly. In the lower left quadrant a loop of the sigmoid colon can be felt, tender to palpation. Digital examination of rectum negative.

*Rectoscopy:* (22 cm.): Mucosa hyperemic and swollen. Stools thick and mushy and contain much bloody mucus, has disagreeable foetor. Negative for dysentery. Positive for Bergen's diplococcus. Vaccines to be made.

*Blood:* H.b. 48 Sahli; erythro. 4,110,000; leuc. 4800; differential, eos. 1; trans. 5; polys. 53; small monos. 34; large monos. 7. Sedimentation after 1 hour 15 mm. Stomach lavage not successful.

March 21: Forty-five minutes after test meal no free acid; total acid 28; pepsin present. Vaccine therapy begun. General diet, but coarse foods forbidden. Given HCL.

April 25: Less tired. Joint pains have disappeared. Less blood and mucus in the stools.

*Blood:* H.b. 50 Sahli.

May 26: Feels better than he has for two years. Defecates every other day, occasionally a semi-solid stool some parts of which contain blood and mucus. Sedimentation after 1 hour 19 mm. *Blood:* H.b. 50 Sahli.

June 30: *Blood:* H.b. 50 Sahli. Feces as on May 26. Vaccinations discontinued.

August 15: *Blood:* H.b. 52 Sahli. Feces as before.

Early in October was admitted to clinic a few days for observation. No subjective complaints. Has daily stool, semi-solid with some blood.

*Rectoscopy:* (22 cm.): Polyposis. Hyperemic mucosa. *X-ray films* ("umbrathor"): Polyposis of descending colon. *Blood:* H.b. 52 Sahli. Again vaccine therapy for a few weeks.

March 10, 1934: Condition unchanged. *Blood:* H.b. 52 Sahli. *Ferrum reductum* one gram 3 times daily. Again vaccination therapy for a few weeks.

May 7: General condition shows no change.

*Rectoscopy:* (23 cm.): Polyps. Mucosa slightly hyperemic. *Blood:* H.b. 60 Sahli; differential; eos. 1; trans. 3; polys. 58; small monos. 35; large monos. 3. Sedimentation after 1 hour 12 mm. Feces thick and mushy with occasional blood.

*Final comments on vaccinations:* In this rather advanced case in which pseudo-polyposis developed, vaccination therapy brings a measure of improvement in general condition.

CASE 9. Mr. S. de L., aged 29, cattle dealer, single. For the past year has noticed blood in his stools, defecations more frequent than normal. For two weeks has been acutely ill with severe diarrhea, the stools often consisting largely of blood. Before defecation and sometimes for about 10 minutes after, there is tenesmus.

*From the notes:* Gives the impression of being ill. Pulse and respiration normal. Mucous membrane good color, teeth show some defects otherwise are well taken care of. Has 3 artificial upper incisors. Tonsils normal. Abdomen flat. Normal tympany. Liver palpable just below the ribs. Slight tenderness in lower left quadrant. No intestinal loops can be felt.

*Rectal examination:* Mucosa feels thickened, examining finger shows blood.

*Rectoscopy:* (22 cm.): Rectal mucosa edematous and bloody. Material removed from rectal wall is negative for diplococci of Bagen.

September 4: Urine positive for urobilin and acetone.

September 7: Patient feels ill. Temperature up to 38.6° C. Defecates 8 times daily. Feces show blood and mucus. Has abdominal pain and tenesmus.

*Blood:* H.b. 78 Sahli; erythro. 5,110,000; leuc. 11,200; differential, immature cells 3; trans. 22; polys. 48; small monos. 20; large monos. 7. Sedimentation after 1 hour 42 mm. Forty-five minutes after test meal, no free HCL; total acid 30; pepsin present. Microscopically nothing remarkable. Stomach contents show no Bagen's diplococci. Is given soft, high vitamin diet and dilute HCL.

September 11: *X-ray films* ("umbrathor"): After filling, the transverse and descending colon appear like a stiff tube. Contours look irregular and saw-toothed. Enema reaches small bowel. Mucosa of the ascending colon and the right part of transverse colon reveal coarse foldings. The distal part of transverse colon and descending colon look like a stiff honeycombed structure. After introduction of air both transverse and descending colon remain narrow and give a marbled appearance.

September 13: Temperature still running up to 38.6° C. Defecates 10 times a day, much blood and mucus. Repeated examining for dysentery and Bagen's diplococcus negative. Second rectoscopic examination: Material from rectal wall shows Bagen's diplococcus. Vaccine prepared.

September 16: *Sensitization tests:* (Storm van Leeuwen): These are all negative.

September 25: Temperature running up to 37.5° C. Defecates 6 times a day. Still much mucus and blood. Vaccine therapy begun.

October 18: Stools thick and mushy, occasional stool shows no macroscopic blood or mucus.

October 30: One or two stools daily. Well formed. Still microscopic mucus.

November 5: Dismissed. To continue the same treatment.

December 15: No subjective complaints. Defecates once a day. Stools normally formed, and contain no pathological elements.

*Blood:* H.b. 78 Sahli; erythro. 4,600,000; leuc. 9200; differential, baso. 1; trans. 3; polys. 57; small monos. 31; large monos. 8. Sedimentation after 1 hour 6 mm.

*X-ray films* ("umbrathor"): Descending and transverse colon show no haustration. Otherwise fairly normal. Loops of small bowel can be felt. Mucosa of transverse and descending colon still show honeycombed appearance. Vaccination discontinued.

February 16: No complaints. Stools normal. Patient not allowed to work.

May 4: No complaints. Has daily stools normally formed, no blood, no mucus.

*X-ray films* ("umbrathor"): Films show normal haustration. Ascending colon shows normal folding, transverse colon still somewhat spastic. Normal folds again beginning to appear in descending colon. Injection of air reveals nothing remarkable.

*Blood:* H.b. 70 Sahli; differential, eos. 1; trans. 4; polys. 59; small monos. 30; large monos. 6. Sedimentation after 1 hour 16 mm. Light work permitted. Was revaccinated for 2 or 3 weeks.

*Final comments on vaccination:* After 5 weeks, clinical symptoms disappeared. After 10 weeks stools show no more pathological elements. After 7 months Roentgen rays reveal only slight departures from the normal.

CASE 10. Mrs. S. V. D. L., aged 53. Was treated in 1925 in the medical clinic for bronchiectasis. Pneumothorax treatments gave improvement. Was first admitted for abdominal complaints March 11, 1930. Had then been troubled for a year with continuous pain in the lower left quadrant. This was more intense just before defecation. Bowels moved rather sluggishly and she generally needed laxatives. No diarrhea. Some blood in the stools during past few weeks.

*From the notes:* There is marked tenderness in the lower left quadrant. The sigmoid colon is palpable. In the mid-line below the navel a painful smooth mass can be felt.

*Rectoscopy:* (15 cm.): No abnormalities seen.

*X-ray films* of stomach and follow-up films of the bowel show no departures from normal.

April 5: Stools thick, mushy. Macroscopically, blood and mucus.

April 12: Forty-five minutes after test meal; no free HCL; pepsin present. No lactic acid. Was given dilute HCL. During her stay here, there was continual complaint of pain in the lower left quadrant.

May 17: Dismissed. To wear an abdominal binder.

September 18, 1931: Report: Still has abdominal pain and tenderness in the lower left quadrant.

August 11, 1933: Readmitted because of persistent abdominal pain in the lower left quadrant. Worse before defecation.

*From the notes:* Pulse normal. Teeth have many defects, some caries. Tongue—papillae not atrophic. Tonsils not enlarged. Trachea slightly deflected to the right. Over the lungs marked evidence of old bronchiectasis on auscultation. Heart slightly dilated to the left. Spleen palpable. In the left iliac fossa a tender band about the thickness of one inch can be felt from above downward.

*Recto-vaginal examination:* Uterus ante-flexed. Rectal mucosa feels thickened, examining finger shows mucus.

*Rectoscopy:* Rectal mucosa looks normal; however, some bloody mucus can be removed with a gauze applicator. This is positive for diplococcus of Bagen. Vaccine prepared.

August 17: Defecates every other day, occasionally a small glycerine enema needed. Feces show hard particles with much bloody mucus, some pus. Microscopic mucus, red cells and leucocytes. Negative for dysentery, positive for Bagen's diplococcus. Forty-five minutes after test meal; free HCL absent, pepsin present. No Bagen's diplococci in the stomach contents.

August 18: *X-ray films* ("umbrathor"): Film shows normal haustration. Contour normal. The enema reaches small gut. Injection of air reveals ulcers in descending colon and sigmoid colon.

*Blood:* H.b. 74 Sahli; erythro. 5,000,000; leuc. 8000; differential, eos. 1; trans. 4; polys. 49; small monos. 40; large monos. 5. Sedimentation after 1 hour 28 mm.

August 30: Autovaccinations begun. Given HCl dilute and cascara. General diet containing no coarse food substances.

September 22: Defecates daily. Takes cascara regularly. Feces thick and mushy with bloody mucus and pus. Still having abdominal pain. Was dismissed to his home to continue treatment.

October 20: Report: Abdominal pain much better. Feels much brighter. Feces thick, mushy and contain mucus.

November 15: Only occasional slight pains in the abdomen. Feces normally formed and contain no pathological substances. Vaccinations discontinued.

December 10: No more pain. Sigmoid colon still slightly painful on pressure.

*Blood:* Sedimentation after 1 hour 12 mm.

February 26, 1934: No complaints. Revaccinated for a couple of weeks.

April, 1934: No complaints. X-ray examination refused.

*Final comments on vaccination:* After 14 weeks all complaints have disappeared, and stools no longer contain any pathological elements.

CASE 11. Mr. J. H., laborer, aged 21, married, admitted to medical clinic November 27, 1933. For the past three months had mucus and blood in the stools. Defecates daily. This is followed for some little time by tenesmus. From time to time sharp pain in the lower left quadrant. Frequently feels very much fatigued. There are no similar cases in this patient's community.

*Physical examination:* Appears healthy. Pulse normal. Teeth, no caries. No defects. Has pyorrhea. Tonsils not enlarged. Heart and lungs normal.

*Abdomen:* Except for some tenderness in the region of descending and sigmoid colon examination nothing remarkable.

*Rectal examination:* Mucosa feels normal, examining finger brings some blood.

*Rectoscopy:* No abnormalities.

*From the notes:* Defecates daily which is followed by some urge. Feces show blood and mucus, much odor. Negative for dysentery, positive for Bagen's diplococcus. Vaccine prepared.

*Blood:* H.b. 63 Sahli; erythro. 5,200,000; leuc. 8200; differential, eos. 2; trans. 3; polys. 48; small monos. 37; large monos. 10. Sedimentation after 1 hour 8 mm. Wassermann negative. Was given *ferrum reductum*, 4 grams daily. Forty-five minutes following test meal; free acid 20; total acid 42.

*X-ray films of colon ("umbrathor"):* The lower part of descending colon and the upper part of sigmoid look tube-like. No intestinal folding observed.

December 18: Vaccine therapy begun. Given a subcutaneous injection every 3 days. Diet, low residue and vitamin rich.

January 9, 1934: Doses 0.1; 0.2; 0.4 cc. vaccine do not cause any rise in temperature, but doses larger than 0.8 cc. bring about a rise up to 39° C. The following dose is then decreased to 0.6 cc. Later the dosage can be gradually increased to 1.2 cc. without any serious temperature rise.

January 23: Defecates daily. Mucus and blood in stools.

*Blood:* H.b. 78 Sahli; reduced iron discontinued.

February 16: Inasmuch as vaccine therapy has produced very little change another culture was isolated from fresh pathological material. New vaccine was then given subcutaneously.

March 6: Stools contain less blood and mucus.

March 16: No more abdominal pain but still some painful tenesmus. Defecates daily. Stools show occasional blood. Vaccinations discontinued. Dismissed. To continue his diet. For the present not allowed to work.

*Final comments on vaccinations:* Vaccination in this case brought very little recovery in 8 weeks. Fresh vaccine, however, resulted in marked improvement in 4 weeks.

CASE 12. Mr. H. Van D. W., 32 years old, farmer, admitted February 16, 1933, to medical clinic. In his 15th year he began to develop a diarrhea, his bowels sometimes moving every hour. At intervals this was less frequent. The stools were watery or thin and mushy containing blood and mucus. After this condition had existed for 2 years patient consulted a specialist who treated him with clysmata and medicines by mouth. A year later the condition was improved to such a degree that rectal medication was discontinued. Had no complaints up to the winter of 1933. At that time, for a couple of days he developed severe diarrhea with watery stools containing mucus and blood. After a few days the frequency diminished to 2 or 3 times a day the stools still containing blood and mucus. Patient felt very tired and had marked distress and a great deal of rumbling in the abdomen which has steadily persisted to date. Generally the stools are thin and mushy but occasionally for a couple of days thick, but all regularly contain blood and mucus. There is no tenesmus. Whenever he comes in contact with corn and also when going to bed (feather-bed) he develops a paroxysm of coughing with a watery nasal discharge, (*rhinitis vasomotoria*).

*Examination:* The patient looks fatigued. Pulse normal. Tongue shows normal papillae. Has one defective tooth. Tonsils normal. Heart and lungs normal. There is slight tenderness to palpation in the region of descending colon. No intestinal loops can be felt. Has rhagades in anal region.

*Rectal examination:* Mucosa normal. Examining finger shows no blood or mucus.

*Rectoscopy:* Negative. Mucosa normal.

*From the notes:* Feces thick and mushy, much mucus and blood, odor. Defecates once or twice daily. No undigested food substances. Negative for dysentery. Bagen's diplococcus positive. Vaccine prepared.

*Blood:* H.b. 75 Sahli; erythro. 4,500,000; leuc. 7900; differential, eos. 2; trans. 4; polys. 65; small monos. 21; large monos. 5. Sedimentation after 1 hour 16 mm.

*Sensitization tests* (Storm van Leeuwen) cutaneous, weakly positive for fish. Intracutaneous for mites and moulds. Forty-five minutes after test meal; no free HCl, no pepsin. Microscopically nothing remarkable.

Stomach contents negative for Bagen's diplococcus. Duodenal drainage. A-Bile, trypsin and lipase normal. Culture for gram-positive diplococci in B-Bile negative.

*X-ray of colon* (barium enema): After filling, sigmoid colon shows no haustration. Contour finely saw-toothed. After injection of air the ascending, transverse, descending and sigmoid colon present a spotted and marbled appearance. The transverse colon at the hepatic flexure gives the picture of a braided band.

April 10: Vaccine therapy begun. Defective tooth extracted. Given HCl and pepsin. No coarse food substances allowed.

May 3: Much improvement. No more abdominal complaints. No more fatigue. Is able to do his work. Defecations and stools as in the beginning of treatment.

June 7: Feels well, has a daily morning defecation. Stools normally formed. Still microscopic mucus. Complains about his anal condition, (rhagades).

July 28: No complaints. Feces normal, no pathological substances present. Vaccine therapy discontinued.

September 9: No complaints. *X-ray films:* Enema reaches the small bowel. In the transverse colon at the hepatic flexure there are no normal transverse folds. The structure as a whole has the appearance of a sponge.

January 15, 1934: Sudden diarrhea twice daily, (a little son developed diarrhea also). Stools thin and mushy

containing mucus. Much abdominal distress. Bargen's diplococci present in the stools.

February 1: Revaccinations begun.

March 26: There has been gradual improvement. Stools normally formed. Vaccinations discontinued.

*X-ray films:* The transverse colon at hepatic flexure now shows normal intestinal fold.

May 14: No complaints. Defecates once a day, sometimes twice daily. Stools normal. Sedimentation after 1 hour 3 mm.

*Final comments on vaccinations:* In this case 3 months after vaccination therapy was begun, the clinical symptoms disappeared. X-ray, however, revealed marked departures from the normal. After 6 months, mucus again appeared in the stools. Revaccination resulted in recovery and the X-ray picture again became entirely normal.

CASE 13. The patient, Doctor S., of Leeuwarden, had been ill for 8 years with long intervals of comparatively good health. Has diarrhea and tenesmus. Stools soft but fairly well formed; contain mucus. In the region of sigmoid colon one can feel intestinal loops which are tender to palpation.

*Rectoscopy:* Marked injection of rectal mucosa. The patient has been on a dietetic regime and treated with clysmata. This treatment proved mildly successful. Vaccination therapy brought about gradual improvement.

CASE 14. The patient, Doctor H., of Assen, had been ill 1 year with diarrhea and tenesmus. Thin mushy stools. Transverse and descending colon palpable and tender on pressure.

*Rectoscopic examination negative:* Stomach contents: No free HCl. Before vaccination treatment was begun, clysmata of "dermatol" had been used without success. Along with vaccination therapy HCl was administered. This treatment resulted in complete recovery.

CASE 15. The patient, Doctor H. P. M., of Groningen, has for the past 4 months had serious symptoms; prior to that time had had some rather indefinite complaints. Generally obstipated. Feces contain mucus and blood. Palpation painful in region of cecum and sigmoid colon.

*Rectoscopy:* Mucosa injected and ulcerated.

*X-ray films of colon:* (Doctor Keyser) Diagnosis: Typical colitis ulcerosa.

*Fractional examination:* Stomach contents: 0/25; 20/40; 25/42; 15/38. No other therapy resorted to before vaccination treatment was begun. Was given soft diet and eventually mild laxatives. Vaccination therapy resulted in complete recovery.

CASE 16. The patient, Doctor v. B., of Tilburg, had been ill 6 months with diarrhea, tenesmus and liquid stools of mucus, blood and pus. Transverse and descending colon are felt and are tender to palpation.

*Rectoscopy:* Mucosa inflamed.

*X-ray films:* Marked departures from the normal in transverse and descending colon. Before vaccination therapy was begun, patient had been on a dietetic regime and had been treated with clysmata. Was given a vitamin rich, low residue diet. Two months after vaccination was begun, there was improvement which still continues. Feces now formed and contain no mucus, blood or pus.

## REMARKS

In order to eliminate the possibility of dysenteric infections, all stools were examined for amoebic and bacillary dysentery. Agglutination reactions according to Flexner, Strong and "Y" were also made on the blood of all patients. These were consistently negative. X-ray films of the colon were taken after the introduction of a contrast mass clysmata.

Results in the 16 patients treated are as follows:

8 completely cured. No. 3 is now symptom free after 10 months. 6 (1 with pseudo-polyposis) show marked

improvement. 2 (1 with pseudo-polyposis) show moderate improvement.

## CHARACTERISTICS OF DIPLOCOCCUS; ISOLATION AND CULTURE METHODS

Bargen describes the organisms found in cases of ulcerative colitis as plump, lancet formed, gram-positive diplococci often growing in pairs and fours. Microphologically they very much resemble pneumococci having a capsule and also having the property of forming short chains in fluid media.

As far as the choice of media is concerned, it may be observed that, as a rule, they grow very well in agar and bouillon. They are, however, semi-anaerobic. Sugar favors the growth very remarkably, therefore, the use of 2% glucose-agar or bouillon is quite general.

Growth is particularly good on blood-agar. Surrounding the colonies grown on this media, we see a hemolytic zone surrounded by a greenish zone. On agar, the colonies are small, round, slightly elevated, grayish and dry and, in some respects, resemble those of streptococcus but differing from those of enterococcus. They differ further from cultures of enterococcus in that they do not grow on gelatin and do not coagulate milk which enterococcus does. Again in contrast with the most common streptococci, diplococci cloud bouillon and give rise to sediment. Diplococci also differ from streptococci and pneumococci in their greater resistance to heat and also in the fact that they are not dissolved in bile but grow very well in this medium. Their growth in Muller's medium and their thermo-resistance we shall mention later. Soon after isolation the diplococci ferment dextrose, lactose, saccharose, maltose, raffinose, salicin, and sour milk. Later these fermentation properties may vary, particularly, in regard to the last six substances mentioned. Diplococci do not ordinarily ferment mannite while the *streptococcus faecalis* does. They differ from the pneumococci in that they do not ferment inulin.

AN ESSENTIAL FOR PROPER IDENTIFICATION IS THE AGGLUTINATION REACTION: Bargen developed agglutination sera with high titers in rabbits which was 10 times greater than that of enterococci. Agglutination with the serum of patients has, according to Bargen, very little differential-diagnostic value, inasmuch as agglutinins are present in only very small quantities. In connection with the differentiation from pneumococci it must be noted that the agglutinating pneumococcus sera of types 1, 2, 3 do not agglutinate these diplococci.

Sensitivity of experimental animals we shall discuss in the section on animal experimentation.

Bargen believes that the portal of entry of the diplococcus is the oral cavity. He finds support for this belief in the observation that frequently they are present in periapical tooth abscesses and in abscessed tonsils.

Differing from the original method which Bargen employed for the isolation of the diplococcus, he advises in his later publications the following method: Material for the cultures should be obtained by rectoscopy. Before this is carried out the bowel should be thoroughly cleansed with castor oil given the evening before, and a couple of warm water enemas in the morning. As far as possible aseptic precautions should prevail. Cotton swabs are brought in intimate contact with the base of ulcers or with the bleeding mucosa. Each swab is immediately placed in warm dextrose brain broth and then put in the incubator for 6 hours. One set of 3 additional tubes of dextrose brain broth is now inoculated with material from each of the two original tubes by shaking the swab into all tubes of each of the sets of three so we now have 3 new cultures of each original 6-hour growth. One set of 3 tubes is heated for 45 minutes at 55 C and placed in the incubator. The other set is incubated immediately. After 18 hours gram-stain preparations are made of the cultures.

From the tube in which the most gram-positive diplococci are found, blood agar preparations are made as follows:

One drop of the tube culture is mixed with 10 cc. of physiological salt solution and one drop of this mixture placed in 10 cc. of blood agar. From this blood agar, later a plate is made. Similar plates are made with several dilutions of the material from the selected tube of blood agar. All these plates are incubated over night. Examination then shows colonies of diplococci surrounded by a greenish zone. Between this zone and the colony there is a hemolytic zone. To isolate a pure culture, material from these plates is again placed in dextrose brain broth for 18 hours at 37° C.

Bargen does not find the organism in cultures of feces but they are frequently present in large numbers in cultures from pus, mucus or blood mixed in the stool.

Buttiau and Sevin, Rafsky and Manheim, Gutierrez, Lastra and Blanco all used Bargen's technique for isolation and culture of the germs. Fradkin and Gray also isolated the diplococcus from material taken from the rectal wall through the rectoscope. This was not always successful at the first attempt and sometimes needed to be repeated. The material they gathered was immediately put in warm dextrose bouillon and placed for 6 hours in the incubator. If gram-positive diplococci were found they made a second culture in dextrose bouillon. If after 12 hours the diplococci were present in this culture, plates of blood agar were made and in 18 to 24 hours the characteristic small, round, slightly elevated, grayish, rather dry colonies of the diplococcus appears. In some cases the cocci have been isolated from the muco-purulent bloody material found in the feces.

*Isolation and culture methods used by the Author:* The rather elaborate isolation method used by Bargen and the difficulties involved in his technique are probably the reasons that many investigators were not successful in isolating the diplococcus of *colitis ulcerosa*. In our work we followed the method of Van der Zoo de Jong whose technique is somewhat similar. In order to eliminate the associated intestinal organisms, he made use of the following cultural characteristics:

(1) As a rule the diplococci can withstand a temperature of 57° to 58° C. for an hour very well. In this they differ from many other bacteria.

(2) While many intestinal organisms grow feebly or not at all in Müller's fluid, the diplococcus grows very well in this medium.\*

*The following materials were used for growing the diplococci:*

(1) Culture tubes with Müller's fluid (not more than a week old).

(2) Tubes of about 10 cc. capacity of heavy glass filled about 2/3 full of 2% glucose bouillon and closed with rubber stoppers. These were especially used for heating.

(3) Culture tubes with 2% glucose bouillon with cotton stoppers.

(4) Culture tubes with well shaken 2% solutions of glucose agar for making plates.

Material for culture obtained by the method of Bargen is now placed in two tubes with Muller's medium, relatively a larger quantity in one tube than in the other.

\*Tetrathionate Bouillon: Four and one-half grams of dry sterilized chalk is mixed in 90 cc. of Bouillon. To this is added 10 cc. of 50% Sodium Hyposulphite Solution (sterilized in live steam) and 2 cc. of the following formula: Iodine 25, Potassium Iodid 20, Aq. Dest. ad 100.

TABLE I

*Bargen's diplococcus was suspended in stomach contents containing no HCL. After incubating for 3 hours, glucose bouillon cultures of the suspension were kept at 37° C. As the following table shows, the bacteria remained alive in almost every instance*

| Name | Free HCL | Total Acidity | Pepsin     | Lactic Acid | Living Bacteria |
|------|----------|---------------|------------|-------------|-----------------|
| B    | 0        | 27            | +          | —           | +               |
| V    | 0        | 26            | +          | —           | +               |
| S    | 0        | 32            | +          | —           | —               |
| D    | 0        | 30            | negligible | —           | +               |
| J    | 0        | 36            | —          | —           | —               |
| P    | 0        | 5             | trace +    | —           | +               |
| V    | 0        | —             | +          | —           | +               |
| K    | 0        | 38            | +          | —           | +               |
| H    | 0        | 6             | +          | —           | +               |
| P    | 0        | 57            | —          | —           | +               |
| R    | 0        | 12            | +          | trace +     | +               |
| d.V  | 0        | 44            | +          | —           | —               |
| B    | 0        | 20            | +          | +           | +               |
| R    | 0        | 14            | —          | —           | +               |

These are then incubated at 37° C. Also two of the stoppered tubes with glucose bouillon are inoculated, again a larger quantity in one than in the other. These are placed in a water bath at about 57° C. and kept at a temperature of 57° to 58° C. for 1 hour. Inoculations from these tubes are then placed in glucose bouillon and from the tube containing the largest amount of material to be cultured, glucose agar plates are also made. At this point all the tubes (including those which have been heated) and the plates are placed in the incubator. On the following day, the presence or absence of diplococci is demonstrated by making gram preparations of all cultures. If no diplococci are found in the heated material, new cultures are again made. Glucose bouillon preparations and glucose agar plates are now made of the tubes containing Muller's medium.

Frequently after the heating and also after the incubating in Muller's medium, diplococci are often present in pure culture. In some cases in which no pure culture can be obtained from Muller's tubes, it is very often possible to get one by introducing a few drops of Muller's solution in glucose bouillon and then carrying out the heating process. The possibility also remains of inoculating Muller's solution with material which has been heated.

One does not consider the result negative until after the cultures examined have been incubated for 48 hours. The more detailed identification of the isolated cocci has already been discussed. If the characteristics of the organisms are those of Bargen's *diplo-streptococcus*, the preparation of vaccine is then undertaken. This should contain about 2 billion bacteria per cubic centimeter.

If isolation of diplococci from mucus, blood or pus in the feces is attempted, it must be remembered that often times fecal material contains organisms which in many respects resemble those of Bargen.

We examined the feces for the diplococcus of Bargen in 12 individuals with no abdominal complaints.

1 case was positive

2 cases in which material was taken from the base of tuberculous ulcers in the colon at autopsy, were negative

2 cases in which material was taken from base of typhoid ulcers at autopsy were negative

One case in which material was taken from the base of a carcinomatous ulcer of the rectum was negative

Feces of 6 patients with rectal carcinoma gave the following results: B-Coli, positive in 2 cases

## Results of Auto-Vaccinations

| Condition when vaccine therapy was begun |                   |                                    |                     |                                   |                                                                                                                                                                                                                           |
|------------------------------------------|-------------------|------------------------------------|---------------------|-----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Name                                     | Length of illness | Stools, Feces                      | Rectoscopy          | Roentgenology                     | Course                                                                                                                                                                                                                    |
| 1. M.                                    | 1 year            | 4 daily, thin, mushy, blood, mucus | bloody, swollen     | descending colon                  | After 9 weeks clinical symptoms cleared up. Four months later more complaints, most likely the results of insufficient after treatment.                                                                                   |
| 2. B.                                    | 6 mos.            | 4 daily, thin, mushy, much mucus   |                     | descending colon, hepatic flexure | Disappearance of all clinical symptoms after 12 weeks.                                                                                                                                                                    |
| 3. P.                                    | 4 years           | 2 daily, mucus, blood, pus         | bloody swollen      | sigmoid colon                     | Disappearance of all clinical symptoms after 10 weeks. Four and one-half months later rectoscopy and X-ray examinations are negative.                                                                                     |
| 4. P.                                    | 9 mos.            | 2 daily, thick, mushy, much mucus  | normal              | descending colon, sigmoid colon   | All clinical symptoms cleared up after 5 months.                                                                                                                                                                          |
| 5. K. L.                                 | 3½ yrs.           | 5 daily, watery, mucus, blood      | bloody, swollen     | transverse colon                  | Clinical symptoms all disappeared after 6 weeks. Eleven months later X-ray examination negative.                                                                                                                          |
| 6. G.                                    | 3 years           | 4 daily, thin, mushy, blood, mucus | bloody, swollen     |                                   | No subjective complaints after 10 weeks. Stools mushy. No pathological substances present. Three months later arthritis with recurrence of intestinal condition. Revaccination gives improvement. Final result not known. |
| 7. M.                                    | 4 years           | thick, mushy, mucus blood          | inflamed, ulcerated | descending colon polypoid         | Temporary improvement. Two and one-half years later, again blood in the stools. Revaccination results in improvement. End result not known.                                                                               |
| 8. Z. W.                                 | 1 year            | thick, mushy, blood, mucus         | hyperemic polyp     | descending colon polypoid         | Some improvement in general condition.                                                                                                                                                                                    |
| 9. L.                                    | 1 year            | 10 daily, blood, mucus             | bloody, edema       | transverse colon descending colon | In 10 weeks clinical symptoms disappeared. Seven months later X-ray examination reveals slight departures from the normal. Rectoscopy negative.                                                                           |
| 10. S.                                   | 4 years           | hard, blood, mucus pus             | bloody              | descending colon sigmoid colon    | All symptoms disappeared after 14 weeks.                                                                                                                                                                                  |
| 11. H.                                   | 3 mos.            | 1 daily, blood mucus               | normal              | descending colon                  | No results for 8 weeks. Fresh vaccine given subcutaneously results in improvement.                                                                                                                                        |
| 12. W.                                   | 6 mos.            | 2 daily, mucus blood               | normal              | transverse colon                  | Clinical symptoms disappeared in 3 months. Six months later again mucus in stools. Revaccination results in recovery and X-ray examination is negative.                                                                   |
| 13. S.                                   | 8 years           | diarrhea, mushy to formed, mucus   | injected            |                                   | Gradual recovery.                                                                                                                                                                                                         |
| 14. H.                                   | 1 year            | diarrhea, thin, mushy              | normal              |                                   | Complete recovery.                                                                                                                                                                                                        |

| 16. v. B.                                | 6 mos.            | diarrhea, blood, mucus, pus        | inflamed            | transverse colon descending colon | Gradual recovery.                                                                                                                                                                                                         |

One case of patient with diarrhea, bloody mucus in stools and many symptoms of allergy (no diagnosis made)

The stools of 15 patients with various types of diarrhea such as:

Paradoxical diarrhea

Diarrhea in tuberculous enteritis

Gastrogenic diarrhea and diarrhea in typhoid fever were examined and one case found positive

If the intestinal lesions are situated low enough for rectoscopic investigations, it is much better to gather the material directly from lesions found on the intestinal wall, using as far as possible aseptic technique. However, inasmuch as the lesions in a number of cases are beyond the reach of the rectoscope, one of necessity, must attempt the isolation of the germ from the material found in the feces.

**Agglutination:** As we have mentioned, agglutination reactions of the isolated cocci were also used for

identification, as well as study of the morphological and cultural characteristics. To that end we carried on agglutinations with rabbit serum from animals which had received a weekly intravenous injection 3 to 4 times with a concentrated emulsion of dead cocci obtained from our autopsy. However, we assured ourselves that this serum did not agglutinate the cocci before our injections were begun.

To agglutinate the different strains of diplococci with specific rabbit serum, tubes were placed at 37° C. for 4 hours and then at room temperature until the following day at which time the end results were noted. (Table 3).

As appears from the preceding table most strains taken from patients with *colitis ulcerosa* showed a strong agglutination while others were negative in this respect. It may be possible that here as also happens with many other organisms, we are dealing with several varieties of the germ. We also followed up the agglutination reactions with a number of strains

TABLE II

*Bargen's diplococcus was suspended in stomach contents containing free HCL. From the table one can observe that in the presence of acid, the bacteria did not live*

| Name | Free HCL | Total Acidity | Living Bacteria |
|------|----------|---------------|-----------------|
| T    | 34       | 58            | —               |

| (Patient Dr. v. B.) | —        | 1 100 +                                           |

isolated from the bowel and stools of individuals in whom there was no evidence of colitis ulcerosa, but which, however, gave the morphological and cultural characteristics of Bargen's diplococcus. Not one of these gave positive agglutination reactions. These tests were done by mixing the bacterial emulsions in different dilutions of the serum, placing for 4 hours at a temperature of 37° C. and leaving at room temperature until the following day at which time the results were read.

**Vaccination:** Patients were generally given a subcutaneous injection every 3 to 4 days of 0.1; 0.2; 0.4; 0.8 and 1 cc. of the vaccine. In this manner the treatment was carried on for not less than 3 months. Vaccination was then discontinued for a few months and again carried out for a couple of weeks. It is recommended that revaccination be repeated at intervals.

In occasional instances, fresh material was isolated from the bowel for the preparation of new vaccine. Circumstances, of course, may make it necessary to make some change in the administration of the vaccine.

#### THE SECRETORY FUNCTION OF THE STOMACH IN ULCERATIVE COLITIS

How the diplococcus causes infection of the bowel is still an open question. Bargen assumed that infected teeth or tonsils might be the focus of infection. Assuming that it is not impossible for the diplococcus to reach the bowel via the stomach, it occurred to us to study the influence of the gastric secretions on the

TABLE III

*Results of investigations on stomach contents of patients having colitis ulcerosa. As it is well known that findings differ very much on different occasions, each case was given a test meal 2 or 3 times. Only those examinations showing the highest values are given in the following table*

| Name           | Age | Free HCL | Total Acidity | Pepsin |
|----------------|-----|----------|---------------|--------|
| M              | 29  | 37       | 72            | —      |
| B              | 15  | 35       | 50            | —      |
| P              | 45  | 0        | 38            | —      |
| P              | 15  | 52       | 72            | —      |
| K              | 36  | 0        | 36            | —      |
| G              | 38  | 0        | 16            | —      |
| M              | 27  | 40       | 81            | —      |
| Z              | 64  | 0        | 28            | +      |
| L              | 29  | 0        | 30            | +      |
| S              | 57  | 0        | —             | +      |
| H              | 21  | 20       | 42            | —      |
| W              | 32  | 0        | —             | —      |
| Patient Dr. H. |     | 0        | —             | —      |
| Patient Dr. M. |     | 25       | 42            | —      |

We favored as far as possible, the use of Boas test meal, considering of course, the patients' daily meals. Stomachs were emptied 45 minutes after the test meal. As it is well known that values differ from day to day, the same tests were done on another day. In Table 3, only the highest figures are given. This reveals that in 8 out of 14 cases achylia was present while in 4 patients, pepsin was absent.

Although from the foregoing, no far reaching conclusions can be arrived at, nevertheless, we felt it necessary to report these findings. At any rate, it is remarkable that in a relatively large percent of the patients no acid was present or low acid values were found.

In all patients we examined the stomach contents for the presence of Bargen's diplococcus, which, however, could not be cultured in a single case.

growth of the diplo-streptococcus and to investigate the secretory function of the patient with reference to the presence or absence of hydrochloric acid and pepsin. We suspended the diplococcus of Bargen in stomach contents containing high acid values, low values, and acid free solutions. After about 3 hours in the incubator, these suspensions were inoculated in glucose bouillon. These were then placed in a temperature of 37° C. In those suspensions containing free acid, the diplococci were found dead. (See Table 2). However, if acid was not present they generally survived. (See table 1). The literature shows that opinions differ very much as to the action of HCl in the stomach contents of such patients. Zweig reports achylia in two cases of *colitis ulcerosa*. He considers it not at all unlikely that absence of free acid in the stomach might favorably influence the development of virulent bacteria in the intestinal tract.

Rosenheim noted improvement in a patient who was given HCl with regular gastric lavage.

Körner and Schaefer frequently found no free acid after a Boas test meal. In some cases low acid values were present. Udaondo found achylia in 3 of 11 cases. Schmidt found normal acid values. Albu attaches no importance to the amount of acid in the stomach, for in his opinion, this is subject to very marked fluctuations.

As we have mentioned, our investigations on stomach contents were directed only to the problem of the presence or absence of HCl and pepsin.

# Hepatoptosis\*

By

CHARLES W. McCLURE, M.D., HERMAN A. OSGOOD, M.D.,

and

J. P. BILL, M.D.

BOSTON, MASSACHUSETTS

THIS communication includes the report of a case of hepatoptosis, i.e., total displacement of the liver; the progress of a gumma of the liver observed fluoroscopically and radiographically, and correlation of data obtained from laparotomy or autopsy findings in cases of hepatoptosis reported by other observers. The latter have described the condition under the synonyms "wandering," "movable," "floating" or "prolapsed" liver. Glénard wrote extensively on this subject in 1899 and credits the first case reported to Cantani in 1866. Ssaweljew (2) states that Heister performed the first hepatopepy.

In the report which follows the displacement of the liver could be positively diagnosed by means of contrast medium, which also permitted observations of changes in the gumma present.

## CASE REPORT

A white housewife, aged 50, complained of pain in the right flank of eight years' duration. The mother, aged 70, was alive and well, as also were two sisters and a brother. The father had died of an unknown cause. There was no family history of cancer, metabolic, cardio-vascular, nervous or mental disease. The history of birth showed delivery to have been normal. The patient had had during childhood, measles, mumps, chickenpox, whooping cough, influenza. The catamenia had begun at twelve and continues to date, of the regular twenty-eight day type. It is symptomless other than for a flow for four or five days. The patient had been married eighteen years but there were no children. There had been no pregnancies, although contraceptive measures were not employed. There is no history of headaches or vertigo. A moderate presbyopia is corrected by glasses. There has been no diplopia, or other visual disturbance. In May and June, 1924, the left eyeball was "very painful." No definite diagnosis of the condition was made by the attending physician. There is no other history suggesting iritis or other ocular disease. The hearing is good. There have been no diseases of the ear, nose or throat. The teeth have all been extracted. There is no history of sore mouth or tongue or of skin lesions or loss of hair. There have been no communicable diseases, such as typhoid fever or pneumonia. About eighteen years ago cholecystectomy was performed, at which time the appendix also was removed. No data concerning the findings are available. This operation relieved attacks of marked epigastric distress of three years' duration. The patient's appetite usually had been good. The bowels had been constipated since childhood. There had been no nausea, no vomiting, no hematemesis, no bloody or tarry stools or jaundice.

In 1923 the patient was coasting on a large sled and was lying prone. Sliding down a steep hill the sled went over

a ledge three feet high. When the sled landed, the concussion to the patient's abdomen caused epigastric pain which radiated through to the back to the right of the tenth to twelfth dorsal vertebrae. The pain persisted about ten minutes, and was so severe the patient stated she "felt as if she were split open." In 1925 the patient had an attack resembling grippe lasting about ten days. During this illness, paroxysmal pain developed under the costal margin in the left hypochondrium. It varied in severity from mild to sharp. It was aggravated by deep inspiration. It bore no relation to food and did not disturb sleep. The pain described was occasionally accompanied by mild pain in the ridge of the left trapezius muscle, in the occipital region and in the right flank at edge of ribs below the right axillary region. There were no symptoms referable to the gastrointestinal, cardiorespiratory, genitourinary or neuromuscular systems. The weight was as usual, 133 pounds.

On physical examination a mass was palpable in the epigastrium. It moved with respiration, was smooth, firm in consistency and moderately tender. Its upper border was beneath the ribs. The lower border extended across the region between the ribs of the epigastric notch. The tumor was interpreted as part of the left lobe of the liver. Otherwise physical examination essentially was negative. Fluoroscopic examination of the chest yielded no evidences of intrathoracic lesions. The diaphragm was normal in position and action. The weight was 126.

Hemoglobin was 90 per cent, red cells 5,000,000 and white cells 6,000 per c. mm. of blood. The stained smear showed nothing unusual. The urine showed no albumin, sugar or pathologic elements on microscopic examination.

In May, 1933, the patient again was examined. During the interim since 1925 there had been no communicable, cardiorespiratory, genitourinary or neuromuscular disease. During the last year the weight had fallen from 134 to 113½ pounds. Since 1925, each year the abdominal pain had been present over a period of two to three months; usually during the late winter. The pain developed without relation to exertion or position, but lying on the right side aggravated it. Often it was "excruciating," persisting a few hours to a few days and was localized in the right flank. The pain was accompanied by abdominal bloating and discomfort. The appetite was poor, the bowels were moderately constipated. There was no nausea, vomiting, water brash, regurgitation, borborygmus, peristaltic unrest or other gastrointestinal symptoms other than the pain and discomfort described above.

Physical examination showed a rather poorly nourished woman not appearing seriously ill. The weight was 51.8 kilograms or 114 pounds. Height was 165.5 cm., surface area 1.5 square meters. The trunk measured 88.9 cm. and the chest circumference 73 cm. The total air capacity of the lungs was 3570 cc. Examinations of the following anatomical regions were essentially negative: pharynx, neck, thorax, breasts, lungs, genitalia, extremities, spine, lymphatic glands, nails, cardiovascular and neuromus-

\*From the Fifth Medical Service of the Boston City Hospital, Boston. Submitted February 10, 1935.

ular systems, and cranial nerves. *The various reflexes were normal. There was no Romberg sign. Station, gait, and coordination were normal.*

*On inspection, the abdomen was full and rounded, whether erect or prone, and the muscles were of normal tone. In the right flank was an oval protuberance 12 cm. long and 5 cm. wide. On palpation the entire right half of the abdomen was filled with a firm, smooth, non-tender, immobile tumor. It extended from the midline of the abdomen to the flank where part of its upper portion formed the protuberance described. The tumor reached to the crest of the right ileum below and above it disappeared under the right costal margin.*

Blood pressure was 100 systolic and 45 diastolic. The heart was not enlarged and showed no auscultatory or other abnormalities. The peripheral arteries were not demonstrably sclerosed. The electrocardiogram disclosed the T. wave to be diphasic in the second lead and inverted in the third. There were no other unusual findings.

The audiogram showed normal hearing for both ears.

Examination of the eyes showed no disease. The pupils reacted to light and accommodated normally. Ophthalmoscopic examination showed yellowish optic discs and the retinal vessels appeared fuller than is usual. The color fields plotted normally.

Basal metabolism was + 7%.

Vital capacity was 106% by Dreyer and 111% by West formulae respectively.

Two 24-hour urine collections gave amounts of 1050 and 960 cc. respectively. They were very slightly turbid, acid in reaction and the specific gravity was 1.010. Both specimens showed a slight trace of albumin and no sugar. The sediment after centrifugalization showed no abnormal microscopic elements. Both ureters were catheterized—the urines from both kidneys showed nothing abnormal microscopically. Nitrogen partition was as follows:

|                 | Total N 4.43 gms. | 5.46 gms.       |  |
|-----------------|-------------------|-----------------|--|
|                 | Amount 1050 cc.   | 960 cc.         |  |
| Urea N          | 3.45 gms. 77.6%   | 4.43 gms. 81.1% |  |
| Uric N          | .10 gms. 2.5%     | .09 gms. 1.7%   |  |

Phenolsulphonethalein excretion in the urine was 59% 59% in 2 hours. These findings are within nonpathological limits.

Hemoglobin was 67% Sahli. Red cells were 4,600,000 and white cells 5,900 per c. mm. of blood. The stained smear showed no abnormal elements. The differential count gave polynuclears 68%, lymphocytes 31% and eosinophiles 1%. Three blood specimens showed positive Wassermann, Kahn and Hinton reactions. Per 100 cc. blood non-protein nitrogen was 28 mgm., urea nitrogen 14 mgm., uric acid 2.5 mgms., creatinin 1.5 mgm. and sugar 104 mgm.

Galactose tolerance was lowered; mellituria occurred after oral administration of both 20 gm. and 10 gm. of galactose. This probably reflected liver functional disturbance.

Duodenal bile was obtained and analysed according to the methods developed by McClure (3). After oleic acid stimulation 50 cc. of pale yellow duodenal bile were obtained. Analyses were made as follows: furfural no., 40; cholesterol, 21 mgm.; alcohol insoluble pigment, 1.5 mgm.; alcohol soluble pigment, 3.0 mgm. These findings show a considerably lowered concentration of bile. This observation and that of lowered sugar tolerance are interpreted as resulting from disturbances of the liver function.

Sigmoidoscopy showed a greatly lessened blood vessel pattern in the rectum with a somewhat grayish mucous membrane. In the sigmoid the blood vessel pattern was absent, the mucous membrane was finely granular and of grayish color. Other than these chronic catarrhal

changes of the mucous membrane, the region was normal.

*X-ray findings were as follows:*

Films of the skull and sinuses were negative. The sella measured 7 by 11 mm. and was regular in outline.

The chest films showed no evidence of substernal thyroid. The heart and aorta were not enlarged. Except for a single discrete calcified area in the left infraclavicular region the lung fields appeared normal.

Intravenous pyleogram showed good function of both kidneys and a normal filling of both pelves and calyces. A slight rotation of the right kidney on its vertical axis was suggested. Retrograde pyleogram showed a very slight blunting of the minor calyces and infundibulum. This was due to overfilling. The size, shape and anatomical position of the kidneys were normal.

Gastrointestinal barium studies showed no evidences of organic lesions in the stomach, duodenum or bowel. However, these organs occupied only the left half of the abdominal cavity.

After barium enema it was found that the hepatic flexure and ascending colon were displaced downward and mesially by a large tumor mass in the right abdomen. This mass extended downward to the level of the upper border of the fifth lumbar vertebra and overlying it the normal shadow of the right kidney could be seen, the lower pole of which was level with the lower border of the third lumbar vertebra. The size and shape and position of the kidneys were within normal limits. The right diaphragm was not elevated and its costophrenic angle was clear.

*Pneumoperitonium* was done by introducing 1000 cc. of air through a trocar. Fluoroscopic examination showed a relatively large gas bubble beneath the dome of the right diaphragm. Films showed no shadows in the regions of the epigastrium and left hypochondrium. However, a shadow interpreted as that of the liver occupied the right half of the abdominal cavity from the edge of the ribs to below the crest of the ilium. Between the upper border of this shadow and the air bubble beneath the right diaphragm lay another shadow of undetermined origin. The diagnoses considered were a cyst, a new growth or coils of small intestine.

Because of the uncertainty of the X-ray diagnosis and because the consulting urologist and consulting surgeon urged removal of the palpable tumor it was considered permissible to administer thorium dioxide. Accordingly the commercial preparation "Thorotrast" was given intravenously and satisfactory contrast films were obtained in the prone position. The liver shadow was rotated downward so that the middle and left lobes lay under the dome of the diaphragm and above the right lobe. The right lobe occupied the right half of the abdominal cavity to beneath the crest of the right iliac bone. Various measurements are given in Table I.

TABLE I.

The measurements of the abdominal cavity, liver and spleen shadows.

|                                                              | Date       |            |
|--------------------------------------------------------------|------------|------------|

Fig. 1.

|                                                    |      |      |
|----------------------------------------------------|------|------|
| Accessory lobes under right diaphragm, transverse: | 12.0 | 12.0 |
| Spleen, transverse:                                | 8.5  | 11.3 |
| Spleen, verticle:                                  | 10.5 | 11.8 |
| Left lobe of liver, vertical:                      | 10.5 | 10.5 |
| Left lobe of liver, transverse:                    | 8.5  | 8.0  |
| Lesion in right lobe, vertical:                    | 7.5  | 3.7  |
| Lesion in right lobe, transverse:                  | 9.4  | 3.1  |

In addition to the measurements given in Table 1, within the enlarged right lobe of the liver was a filling defect measuring 7.5 cm. by 9.4 cm. The margins of the area were sharply defined. These findings are readily discernible in the reproduction of the X-ray film (see Figure 1).

The spleen was well outlined on the film. The left border was prolapsed from the diaphragm so that it occupied a position in the mid portion of the upper left abdominal quadrant. The upper pole reached the dome of the diaphragm. It was apparently rotated so that the left border lay anteriorly, as is shown in Figure 1.

*The diagnoses made were:* Displacement of the liver, i.e., total hepatoptosis; tertiary syphilis and gumma of the liver. The trauma was considered the cause of the hepatoptosis and the gumma an incidental finding. The contrast films of the liver, excluding the area of the tumor, showed no defects in the liver substance. This finding goes far to eliminate cirrhosis.

The patient was not given antiluetic treatment until the fall of 1934. This was for the purpose of ascertaining the effects of measures designed to influence the disturbed state of the liver function (4); i.e., the weekly intraduodenal administration of 25 cc. of 33% magnesium sulphate solution. Coincidentally the food intake was augmented. These therapeutic measures were followed by a gain of 33 pounds in weight, disappearance of all subjective symptoms and non-recurrence in 1934 of attacks of pain which had regularly occurred each spring for the past eight years.

Intramuscular administration of bismuth salicylate was instituted in September, 1934. One gram of potassium iodide, the tolerance dose, was ingested daily. Fifteen

Fig. 1. This illustration shows the liver occupying the right abdominal cavity; the left lobe is beneath the right leaf of the diaphragm and the lower border of the right lobe extends below the crest of the ilium. The negative shadow within the right lobe represents a gumma. The spleen is outlined beneath the left leaf of the diaphragm.

weeks later a second contrast film was taken. During this period 1.95 grams of bismuth salicylate and 105 grams of potassium iodide had been administered. The changes occurring in the liver are portrayed in the reproduction of the X-ray film (Fig. 2) and in Table I, under November. The changes consist in a definite decrease in the size of the liver and an almost complete disappearance of the gummatous area. The development of these changes had been observed through the fluoroscope by which means progressive increase in density of the liver's shadow was also noted. The position and rotation of the liver remain essentially unchanged.

### DISCUSSION

Various authors describe symptomatology due to displacements of the liver. However, their descriptions are based partly on the findings in cases in which the diagnosis was not proved by laparotomy or autopsy or the use of "Thorotrast." It takes but little experience to teach one that the clinical diagnosis of this condition is fraught with great chances for error. For this reason it is unsafe to correlate the symptoms presented except in those cases in which the diagnosis has been proved objectively. Therefore, the writers have considered it necessary to correlate the symptomatology presented by reported proved cases.

Seventy cases (5 to 51 and 53 to 57 inclusive) of total hepatoptosis, in which the diagnosis was confirmed on laparotomy or autopsy, have been collected. Of the 70 cases only six were men; thus the condition is largely confined to women. The condition was most common between the ages of twenty to fifty, by far the greatest number occurring between the ages of thirty to forty; the youngest was twenty (18) and the oldest sixty-seven (15). Pregnancy had preceded the symptoms in thirty-three of the sixty-four women. In nine the symptoms had developed suddenly and immediately following trauma or unusual physical exertion. Trauma was the apparent cause in our case. Paralysis of the right leaf of the diaphragm due to diphtheria was considered to be the cause in one case (10). The condition was congenital in one case, a mesohepar being found (38). The cause was not discussed in the remaining twenty-six cases. However, with few exceptions these patients were described as splanchnoptotic. This state predisposes to hepatoptosis because pressure of the gastro-intestinal tract is a potent factor in supporting the liver in its normal anatomical position. Obviously, such support is diminished in direct proportion to the degree of laxity of the muscles of the abdomen. Various ligaments are also instrumental in holding the liver *in situ*; principally the lateral, coronary and falciform. Stretching or possibly tearing of these ligaments due to trauma predisposes to displacement of the liver. Such trauma may be incident to violent physical exertion as lifting (26) or carrying a heavy load (16), to jarring as was evidently the cause for the displacement reported here and also by Michl (9) and Langenbuch (10) to blows on the right side (51) or to squeezing of the viscera, as occurred in a case reported by Howell (37) in which a horse rolled over a soldier's abdomen. Thus the usual apparent causes reported for displacement of

Fig. 2. This illustration shows the diminution in the size of the liver and the almost complete disappearance of the gummatous area resulting from antiluitic treatment.

Fig. 2.

the liver are loss of tone of the muscles and trauma to the contents of the abdomen. More rarely the condition is congenital or possibly due to paralysis of the diaphragm.

The case records were often not described in detail; for which reason the frequency, especially of milder symptoms, can not be stated with accuracy. However, the symptoms were sufficiently well described to permit of the establishment of the general symptomatology of the condition.

Of fifty-three uncomplicated cases in which the duration of symptoms was stated it varied from one week to twenty-two years. However, in nearly half the cases it varied from one to two years. The onset was characterized by marked subjective symptoms in twenty-nine while in seventeen the initial symptoms were mild and eventually became more severe. The time of development of the ptosis of the liver is obviously uncertain. Occasionally the patient had observed an abdominal tumor for a considerable period before onset of subjective symptoms, in one case for four years (32). The onset of severe pain and the finding of a palpable tumor which have been observed immediately following strenuous physical exertion or trauma suggest that the ptosis may have an acute onset, as was discussed above.

**Pain.** Fifty-three cases presented hepatoptosis as the sole organic lesion found on laparotomy or autopsy. Of these abdominal pain occurred in forty-seven. The abdominal site of pain was confined to the epigastrium in seven, to the right hypochondrium in twenty-eight, to both these regions in five, to the right hypochondrium and lower abdomen in three, and to the lower abdomen in five. In thirteen of these with upper abdominal pain the latter radiated to the dorso-lumbar back, to the shoulder blades, to the ridge of the trapezius muscle of the right neck, or down the right thigh. The upper abdominal pain was described as of severe paroxysmal character in two, as persistently severe in one and as mild in three. In one case (6) the epigastric pain developed an hour after partaking of food. In six the severe type of pain was at times replaced by mild pain or a sensation of dragging or drawing. This sensation of dragging or drawing was the only abdominal discomfort experienced by two other cases. In three of these there were no symptoms but attacks of vomiting occurred in the three other cases. In one case the lower abdominal pain was described as of severe colicky nature. In eight cases exertion aggravated the pain while reclining relieved it. In three of these eight cases bending produced a sensation of intra-abdominal pressure.

The experimental observations of Steele (52) on cadavers indicate that the abdominal pain may result from kinking or torsion of the cystic or common ducts due to the dropping of the anterior portion of the liver. However, in the case reported here the pain occurred only at one season of the year and this obscures the explanation of its mechanism. Jaundice developed in seven cases in which severe pain occurred in either the upper or lower abdomen, and in another case in which the pain was mild. Jaundice developed in one other case characterized by chills and

fever (19) and in which abdominal pain did not occur. In another case (15) the chills and fever were accompanied by abdominal pain but jaundice did not develop.

**Associated symptoms and signs.** In two cases (6, 48) attacks of hematemesis and melena occurred; in these, upper abdominal pain was a prominent symptom. One case (32) presented dyspnoea and mild cough, in addition to attacks of severe epigastric and dorsolumbar pain. Attacks of gross hematuria occurred in one case (15), great frequency of urination in another (26) and scalding urination in a third (20). In another case (46) oliguria was followed by polyuria in a manner comparable with that which may occur in intermittent hydronephrosis. On laparotomy no kidney lesions were found in these four cases and the urinary symptoms were relieved by hepatoxy. In two cases (32, 42) light edema of the lower extremities was present. In another case (31) paroxysmal attacks of tachycardia occurred which were relieved after hepatoxy. Vomiting was a prominent symptom in sixteen cases, in only one of which (19) was abdominal pain absent. In one of these (31) vomiting was frequent and on various occasions "gastric peristaltic waves were plainly visible" on inspection of the abdomen. At laparotomy the stomach and intestines of this case (31) appeared to be normal. The vomiting and visible peristalsis were interpreted as the result of occlusion of the pylorus due to pressure of the displaced liver on the stomach. Anorexia, diarrhea, bloating and other dyspeptic symptoms were present in twenty-one cases. The general or nervous symptoms, headache, lassitude, malaise, nervous irritability, dizziness, fatigue, cold and hot flashes, insomnia, melancholia, were present to well marked degrees in thirteen cases. In three cases (5, 19, 22) there were no subjective symptoms.

Thus the symptoms presented by fifty-three uncomplicated cases may be classified as:

1. Hepatic; *i.e.*, pain, jaundice, chills, fever.
2. Gastro-intestinal; *i.e.*, nausea, vomiting, anorexia, diarrhea, constipation, obstipation, hematemesis, melena.
3. Cardio-respiratory; *i.e.*, dyspnoea, cough, edema, tachycardia.
4. Genito-urinary; *i.e.*, hematuria; great frequency urination; dysuria.
5. General; *i.e.*, headache, malaise, lassitude, weakness, nervous irritability, dizziness, fatigue, cold and hot flashes, insomnia, melancholia.
6. Latent; *i.e.*, no subjective symptoms.
7. Accessory or secondary: sensation of tumor in abdomen on bending (6); pain aggravated by exertion and relieved by reclining.

Both abdominal pain and jaundice occurred in sufficient numbers of uncomplicated cases to establish them as symptoms and signs resulting from the displaced liver. Chills and fever without jaundice but with pain was recorded in but one patient. However, repeated attacks of these symptoms were relieved entirely by hepatoxy, at which operation no other pathology were discovered. The gastro-intestinal symptoms may all be logically explained as due to pressure of the displaced liver and interference with the portal circulation. The genito-urinary symptoms enumerated were well marked in the four patients in which they were observed. While pyleograms were not done; at operation no pathology other than the displaced liver was found and hepatoxy entirely relieved the symptoms. These findings indicate that the displaced liver, possibly through pressure phenomena, produced these urinary symptoms. There is no reasonable doubt but that the accessory or secondary symptoms described were the result of the liver's abnormal position. Obviously, the explanation of the general symptoms is problematical. They also were relieved by hepatoxy and this finding indicated that the symptomatology described was incident to displacement of the liver. Dyspnoea and cough on exertion occurred in one case (32) and paroxysmal attacks of tachycardia (31) in another. In both cases hepatoxy was followed by disappearance of the symptoms. However, neither the pulmonary or cardiovascular systems were subjected to radiographic, electrocardiographic and other searching studies which are necessary to rule out disease. For this reason the findings merely suggest that the pulmonary and cardiac symptoms described resulted from displacement of the liver. Nevertheless these symptoms of dyspnoea, cough and tachycardia may logically be explained as due to disturbances in cardiac action resulting from traction of the vena cava on the heart as a result of the pull of the displaced and mobile liver. In two other cases mild, but definite, edema of the lower extremities occurred. Hepatoxy relieved the edema in one case (45). The other case (39) came to autopsy and no cardio-vascular pathology was found. In both these cases the edema is explained as resulting from pressure or a kinking of the inferior vena cava.

In fifty-three uncomplicated cases the liver was not demonstrably diseased. In a fifty-fourth case (38) an old gumma was found which in no way influenced the subjective or objective symptomatology. This finding is comparable with that in the case reported in this communication. In another, the fifty-fifth case, au-

topsy disclosed uniformly distributed atrophy of the liver cells incident to the obstructive jaundice. The latter was due to kinking or torsion at the commencement of the common bile duct. In three cases the liver, *i.e.*, an abdominal tumor, was not palpable. In the fifty uncomplicated cases in which the liver was palpated, it occupied the right upper abdominal quadrant in twenty-three; it reached into the midabdominal quadrant in ten and occupied the entire right side of the abdomen in twelve. It was palpable in only the right lower abdominal quadrant in five cases. The liver was described as freely movable on palpation in twenty-six cases, as smooth in six, hard in six and soft in two, an edge was felt in one and a notch in another; it was tender on palpation in two and moved on respiration in three cases. Unusual descriptions of palpatory findings were that the tumor was "fist-sized" in three cases and the "size of a child's head" in another. The usual area of liver dullness over the lower anterior chest was replaced by a tympanitic note in five cases. In two of these, pushing the abdominal tumor up under the right ribs brought about a change in percussion note from tympany to dullness (40, 39).

In twenty-seven of the uncomplicated cases the mobility of the palpable abdominal tumor; *i.e.*, the liver, was not described. However, on laparotomy or at autopsy the liver was readily replaced in its normal or nearly normal anatomical site. From this finding it is inferred that the liver palpated preoperatively as an abdominal tumor was freely movable in these cases. Thus, mobility of a palpable abdominal tumor in the right side of the abdomen is the usual finding in hepatoptosis. Tenderness on palpation was noted in but two cases which permits the deduction that the ptosed liver is usually not sensitive to ordinary palpation. The liver of the case reported here was not tender on palpation.

Thus, the usual findings in hepatoptosis may be summarized as a freely movable, non-tender tumor occupying the right abdomen. The upper border is usually under the right rib margins and the lower border anywhere from the mid portion of the right hypochondrium to below the crest of the right ilium; the entire tumor may be situated below the costal margins, even in the right lower quadrant. While the tumor mass usually appears large, it may occasionally on palpation be apparently as small as a "fist." Rarely, no tumor is palpable. When occasionally there is absence of normal liver dullness over the lower right chest such dullness may be returned by pushing the tumor up under the margins of the ribs on the right.

Eleven incorrect preoperative diagnoses were made, which are as follows: hydronephrosis (34); floating kidney (9, 10, 11, 20, 22, 25); tumor of gall bladder (36); gall stones (36); enlarged liver (9, 36); echinococcus cyst (7, 25, 32); liver abscess (19); cancer of the liver (32); tuberculous typhlitis (14); renal tumor (49); and subdiaphragmatic abscess (44).

The following complications were demonstrated in sixteen of the seventy cases: chronic cholecystitis (6); pericholecystitis (6); cholelithiasis (9, 44, 46, 49); duodenal ulcer (6); cirrhosis (13, 21, 7, 22); single cicatrized gumma (38); hydatid cyst (44); cancer (51); duodenal ulcer with pyloric stenosis (53); floating kidney (20, 50, 55); hydronephrosis (8). In another case, as already described, atrophy of the liver parenchyma was found.

All but a relatively few of the cases which have been correlated were subjected to some form of hepatopepy; the results of which were highly favorable. Comparable conclusions are reported by Treves (57), Ssaweljew (2), Werner (8) and others who have collected the postoperative results of published hepatopepies.

### SUMMARY

A case of hepatoptosis is reported in which the positions and anatomical characters of the various intra-abdominal organs were definitely established by X-ray films of the untreated abdomen, by pyelography, by barium gastrointestinal studies and by pneumoperitoneum. The exact positions of the spleen and liver were established by contrast X-ray films after intra-

venous administration of "Thorotrast," a colloidal suspension of thorium dioxide. By means of this contrast medium, other than for a gumma, anatomical lesions such as cirrhosis were probably excluded. This medium permitted radiographic demonstration of diminution in size of the liver and the contained gummatous area resulting from antiluetic treatment.

Fifty-three uncomplicated cases of hepatoptosis, or total displacement of the liver, have been collected from the literature and the described symptomatology correlated.

The reported results of hepatopepy indicate that the operation is an efficient measure for relieving symptomatology.

# Liver Function in Hepatic and Extrahepatic Diseases\*

## II. Clinico-pathological Correlation and Evaluation of the Usefulness of Liver Function Tests

By

and

Wm. J. KERR, M.D.  
SAN FRANCISCO, CALIFORNIA

**I**N the course of our liver function studies\*\*, 29 of the patients had abdominal operations with biopsy of the liver, or came to necropsy. This made possible a study of the relationship between the histologic structure and the function of the liver as determined by liver function tests.

### A. INTRINSIC DISEASES OF THE LIVER

The greater proportion of patients in this group (Table I) had a biliary type of portal cirrhosis; the remainder were examples of toxic cirrhosis. Banti's disease, hemochromatosis, syphilis of the liver, and diffuse scarring of the liver following old and recent portal thrombosis.

In all of these patients there was abnormal retention of the dye. The modified glucose tolerance test was markedly positive in the four patients in whom it was performed. The two patients who showed the most marked impairment of excretion of the dye also showed the greatest degree of structural alteration of the liver. These two case histories are presented in more detail:

D. W., No. 42, a white female, 33 years of age, was observed in the University of California Hospital and in the Out-patient Department for a period of ten months, beginning April, 1932. She had contracted syphilis in 1926, and was treated intermittently with bismuth and arsenicals. Several months before entry into the hospital on June 13, 1932, the patient received 25 injections of neoarsphenamin in another clinic. She had consumed an excessive amount of alcohol over a period of many years. At entry, examination showed icteric skin and sclerae, a markedly enlarged liver, and a slightly enlarged spleen. The Rose Bengal test was 88 and 86 per cent of the standard at 8 and 16 minutes, respectively. The icterus index was 20. The jaundice subsided after one month and did not recur. She had numerous small esophageal hemorrhages, and 10 months after entry died, following a massive hemorrhage. The last of three Rose Bengal tests was done 2 months before death, showing a retention of 82 and 70 per cent of the dye at 8 and 16 minutes, respectively. The icterus index at the same time was 12 units. At autopsy the liver weighed 2050 grams, was finely

nodular throughout, and yellowish-white in color. The histologic structure, as shown in photomicrograph No. 1, is that of a toxic cirrhosis.

C. P., No. 65, a white male, 50 years of age, entered the University of California Hospital on August 22, 1933, complaining of jaundice, swelling of the abdomen and edema of the ankles, increasing in severity over a period of two months. For the past 30 years he had consumed a quart of wine daily. On examination, he had an icteric skin and sclerae, and evidence of collateral circulation in the flanks and over the abdomen. Even after removal of 4500 cc. of fluid from the abdomen, the liver and spleen were not palpable. There were external and internal hemorrhoids. The Rose Bengal readings were 82 and 79 per cent at 8 and 16 minutes. The icterus index was 60. During the residence in hospital he had several episodes of hematemesis and died following rupture of an esophageal varix. At autopsy the liver weighed 1900 grams, had a yellowish-green color, and was composed of nodules 1 to 2 mm. in size, which completely replaced the normal architecture. Photomicrograph No. 2 represents the histologic structure of the liver. The diagnosis was biliary cirrhosis.

In four patients, clinical examination failed to reveal indications of hepatic insufficiency, although an enlarged liver and spleen were present. The Rose Bengal test showed abnormal retention of dye in all these patients, and the modified glucose tolerance test was strongly positive in one. Subsequent examination of the liver bore out the accuracy of the tests. The salient features of the four case histories are noted:

J. T., No. 91, a 41 year old white female, entered the University of California Out-patient Department on July 1, 1932, stating that she had accidentally noticed a large mass in the left upper quadrant of her abdomen. There were no other complaints. A diagnosis of syphilis had been made in 1909, and she had been treated with several mercury rubs. Examination showed an enlarged, irregular liver, and a greatly enlarged spleen extending almost to the iliac crest. The blood Wassermann reaction was positive. The Rose Bengal test showed retention of 66 and 50 per cent of the dye at 8 and 16 minutes. The patient was treated with potassium iodide, mercury salicylate and bismuth, with no reduction in the size of the liver or spleen. A splenectomy was performed on November 10, 1932, and a biopsy of the liver was taken at the

\*\*See Part I, The Results of Clinical Experience with 326 Cases. Submitted January 8, 1935.

Fig. 1

same time. At the time of operation, the Rose Bengal test readings were 65 and 44 per cent, respectively. The modified glucose tolerance test showed a minimum blood sugar of 52 mg. per cent and a fall of 46 mg. per cent. The icterus index was 8 units. The pathologic diagnosis was syphilis of the spleen and liver. Following the operation, retention of Rose Bengal increased to 78 and 52 per cent, respectively. Since that time the patient has been treated with bismuth and potassium iodide, and examination on June 1, 1934 revealed the liver to be palpably enlarged, but with a smooth edge. The lost Rose Bengal test gave readings of 60 and 40 per cent, respectively. Figure No. 3 shows the microscopic appearance of the liver at the time of operation.

H. K., No. 64, a 51 year old white male, first entered the University of California Hospital on January 7, 1933, complaining of slight dyspnea which occasionally came in paroxysms with orthopnea; and substernal pain. He had been given digitalis since July, 1932. Syphilis was denied. Examination showed the classical signs of aortic insufficiency due to probable aortic valvulitis. The liver and spleen were greatly enlarged. The Rose Bengal test showed retention of 70 and 50 per cent of the dye at 8 and 16 minutes. In September, 1932, a positive blood Wassermann reaction was found on examination in the Out-patient

Fig. 1. (Case No. 42, Table 1). Liver from a patient with toxic cirrhosis. The section shows atypical regenerating hepatic lobules situated in scar tissue. X 100.

Department, and specific treatment started. The patient became irrational and committed suicide on June 24, 1933. At autopsy the gross appearance of the liver suggested chronic passive congestion. However, microscopic examination revealed a picture of early biliary cirrhosis, as indicated in photomicrograph No. 4.

D. B., No. 72, a white male, 17 years of age, had been observed in this hospital since April, 1931. At that time he entered, complaining of intermittent pain in the left upper quadrant of the abdomen for a period of one year, becoming more severe during the previous four months. He was born in Italy and had entered this country when four years old. Examination revealed a greatly enlarged, firm spleen. The liver was not palpable. The white blood count during the first entry varied around 3000 cells per cu. mm. The Rose Bengal test gave readings of 62 and 50 per cent, respectively. The icterus index was 7. He re-entered the hospital after two years with the same complaints. He had gained 31 pounds. The spleen had enlarged slightly; the liver edge was not palpable. His white cell count was 3400 cells per cu. mm. The ability of the patient to excrete Rose Bengal and the icterus index were practically unchanged. A splenectomy and biopsy of the liver were performed on March 7, 1933, and the pathologic diagnoses were "spleen compatible with Banti's disease, and peri-portal cirrhosis of the liver". The latter is illustrated in photomicrograph No. 5.

F. C., No. 252, a 45 year old white Italian male, entered the University of California Hospital in February, 1931, complaining of weakness and pallor of seven months' duration. Examination revealed an icteric skin and a palpably enlarged spleen. Laboratory studies showed an anemia, and indicated that the condition was a chronic hemolytic icterus, probably of the acquired type. A splenectomy was performed on February 6, 1931. Following this the patient remained anemic, notwithstanding liver and iron therapy, but he did not require blood transfusions. He had occasional crises of deglobulinization. The Rose Bengal test gave readings of 59 and 39 per cent in June, 1933, and of 70 and 52 per cent in October, 1933. On

\*2 years later.

Note: In case of repeated tests, the results of the test nearest to the date on which the pathological specimen was obtained, are given.

Fig. 2. (Case No. 65, Table 1). Liver from a patient with biliary cirrhosis. The section shows atypical hepatic lobules associated with marked bile-duct proliferation. X 50.

March 16, 1934, he developed fever with constant epigastric pain and increasing weakness. This persisted for three weeks. During this time the red blood count varied between 980,000 and 2,500,000 cells per cu. mm. Death occurred April 5, 1934. The autopsy showed old and recent thrombosis of the portal, splenic and mesenteric veins. This process extended into the liver, producing numerous small scars. The original thrombosis probably followed the splenectomy in 1931, and caused the focal scarring of the liver. Recanalization then took place, followed by thrombosis as a terminal feature. The effect of the scarring process manifested itself by a decreased excretory function late in 1933, and if another test had been performed in 1934 a still greater retention of the dye probably would have been observed. Photomicrograph No. 6 shows the scarring, together with the recent and old thrombosis of the portal vein.

#### B. OBSTRUCTION OF THE COMMON BILE DUCT

The livers of five patients in this group who had tests of hepatic function, were examined pathologically (Table II). Primary carcinoma of the common bile-duct with complete occlusion was found in patients No. 144 and 152. In patients No. 60 and 156, the obstruction was due to gall-stones in the common duct. The obstruction was complete in the former patient, partial in the latter, in which the liver was also seeded with metastases from a carcinoma of the gall-bladder. In patient No. 6, a biopsy of the liver gave evidence of biliary obstruction, but an exploratory operation failed to reveal its cause. The clinical diagnosis was catarrhal jaundice. The Rose Bengal test showed impaired hepatic function in all five patients of this group, as did the modified glucose tolerance test in the four patients examined.

#### C. NEOPLASMS OF THE LIVER

In patients No. 164 and 147 (Table III), the livers were seeded with metastatic carcinoma, but there was no evidence of common duct-involvement. A slight obstruction of the intrahepatic bile-ducts had caused jaundice, as shown by the icterus index. In patient No. 153, the metastases were very few and there was

Fig. 2

normal excretion of Rose Bengal and no jaundice. A very diffuse primary endothelioma, simulating metastatic carcinoma in its gross appearance, was found in patient No. 326. The extreme distortion of the hepatic parenchyma, with intrahepatic bile duct obstruction produced by the neoplasm, had caused marked retention of the dye. In patient No. 178 the portal spaces were involved by a leukemic process, but the hepatic parenchyma escaped.

#### D. EXTRAHEPATIC DISEASES

The group of patients listed in Table IV served as controls, since pathological examination of their livers showed no primary hepatic involvement. All but one had a normal liver function, as measured by the Rose Bengal test. Patient No. 240 had a definite retention of the dye, but a biopsy of the liver showed this organ to be normal. The pertinent facts of this case history are summarized below.

E. C., No. 240, a white female, 38 years of age, entered the University of California Hospital in January, 1934, complaining of anemia of 12 years' duration, associated with intermittent pain in the right upper quadrant, tingling of the arms and legs, nausea, and "yellow-skin". The anemia had been variously treated, without improvement. Examination revealed a palpable liver edge and edema of the ankles. The red blood count varied between one and two million red blood cells per cu. mm., and slowly rose to three million. A ligation of the splenic artery was performed on April 7, 1934, and a biopsy of the right lobe of the liver was taken at that time. The liver had a normal gross appearance, but was slightly enlarged when examined during the operation. Its histologic structure was normal. The clinical diagnosis was anemia of undetermined etiology. The Rose Bengal test at that time gave readings of 80 and 51 per cent, respectively. The icterus index was 12 units. Four months later, with an improvement of anemia, the Rose Bengal elimination increased, the readings being 66 and 46 per cent at 8 and 16 minutes.

In patient No. 198, an hepatic lesion was suspected on clinical grounds, but the Rose Bengal test was normal. At autopsy, the liver was found to be normal.

Fig. 3.

Fig. 3. (Case No. 91, Table 1). Liver from a case of syphilis with hepatic involvement. The section shows syphilitic granulation tissue surrounding an hepatic lobule. X 100.

| 156      | Metastatic carcinoma of the liver   | 16            | 73%              | 55%     | 59                              | 43    | Carcinoma of the gallbladder; choledocholithiasis                | Autopsy            |

The important findings of this case history are as follows:

C. H., No. 198, a white male, 48 years of age, entered the University of California Hospital in February, 1934, in a state of delirium of two days' duration. It was said that he had consumed large quantities of alcoholic liquors until two years ago; since then he had been on only occasional sprees. Examination revealed a markedly undernourished and dehydrated male in acute delirium, with hallucinations. The liver edge was barely palpable. The blood and spinal fluid Wassermann reactions were negative.

gestion of the liver was found in patients No. 282 and 289. In the latter patient, the passive congestion was recent and slight. In the former, marked sclerosis around the central vein, resulting from cardiac decompensation over a period of two years, caused no alteration in the excretory function of the liver. This case suggests that the excretory function of the liver need not necessarily be altered, even in advanced congestive heart failure. In patient No. 303, terminal focal necroses of the liver were found.

#### DISCUSSION OF RESULTS

Pathological retention of Rose Bengal dye in dis-

TABLE III

Urobilinogen by the Wallace and Diamond test (1) was present in the urine in 1:30 dilution. The icterus index was 15, and the Rose Bengal test was normal. The patient's condition became rapidly worse, and he expired after 14 days. At autopsy, there were no important findings. The liver showed no pathologic alteration.

In several others, as noted in Table IV, the following abnormalities were present: A terminal disseminated tuberculosis in patient No. 251, which probably had not been present four months before death when the test had been performed. Chronic passive con-

eases of the liver, without jaundice, is seen only in the presence of diffuse intrahepatic lesions. Moreover, retention of the dye is apparently proportional only to the degree of structural change of the hepatic parenchyma. Therefore, types of hepatic lesions cannot be differentiated by this test.

Complete obstruction of the common bile-duct produces a high icterus index and a marked degree of dye retention. The latter increases with the duration of the block, indicating that distortion of hepatic parenchyma and possibly injury to the local components of the reticulo-endothelial system also plays a part. In

Fig. 4

patient No. 58, following a prolonged obstruction of the common duct, the retention of the dye increased, in spite of the fact that the block had been released in the interim, indicating secondary parenchymatous damage which was verified at autopsy. Photomicrograph No. 7 shows details of the liver in this case. This indicates how intimately biliary obstruction is related to parenchymatous damage, and explains why extrahepatic and intrahepatic block cannot be differentiated by liver function tests except immediately after onset, and then only by means of tests based on the metabolic activity of the liver.

Neoplasms of the liver which do not obstruct the bile-ducts, may cause no abnormality in the excretory function. Neoplasms impinging on intra—or extra-hepatic bile-ducts cause retention of the dye, and jaundice, in proportion to the degree of obstruction. This parallelism between the icterus index and the Rose Bengal test was already pointed out in the analysis of clinical results.

Among the 29 patients who had a Rose Bengal test and a histological examination of the liver, only one, a case of severe anemia, showed the combination of pathological dye retention and normal hepatic parenchyma. Among the same patients, only one, a case of severe chronic passive congestion, had a negative Rose Bengal test in the presence of structural changes in the liver. There was, thus, a 93 per cent agreement between the dye excretion test and the pathological examination. The modified glucose tolerance test was performed with positive results in 8 patients of this series, and in every case anatomical disease of the liver was present.

#### AN EVALUATION OF THE USEFULNESS OF LIVER FUNCTION TESTS

The study of hepatic function for clinical purposes occupies a rather unique position: After investigations extending over a period of about 40 years, the clinical usefulness of liver function tests has been neither generally accepted or universally rejected. The same statement applies in an even greater measure to individual tests of hepatic function. One of the reasons for such a conflict of opinions is that the aims

Fig. 4. (Case No. 64, Table 1). Liver from a patient with early biliary cirrhosis. The section shows distortion of hepatic parenchyma due to inflammatory reaction in and around the portal spaces. X 100.

and limitations of functional examination of the liver are often not completely realized.

The primary object of hepatic function tests is to detect the presence of functional insufficiency of the liver and to measure its degree. Even an ideal liver function test is not suitable for determining the *cause* of hepatic insufficiency, except by deduction, and therefore should not be expected to furnish diagnoses. Moreover, as amply demonstrated in our first paper, the presence of impaired hepatic function does not necessarily indicate the existence of a primary disease of the liver. Neither does a negative outcome of one or several liver function tests always mean absence of hepatic disease.

Functional testing of the liver has been of service in three respects: 1. In supplementing other methods of studying patients with known or suspected diseases of the liver; 2. In revealing the presence of secondary hepatic insufficiency in a variety of extrahepatic diseases in which formerly no such involvement of the liver was suspected. Consequently our understanding of the pathological physiology of these diseases has been enhanced; 3. As an important safety-measure before certain potentially dangerous therapeutic procedures are instituted. Among these are particularly cholecystectomy (2), thyroidectomy, major surgical operations in the presence of hepatic disease (3), and the administration of arsenicals in syphilis (4). When the existence of considerable hepatic insufficiency is established, conservative treatment or appropriate pre-operative preparation consisting of a period of glucose therapy (5), will avert or minimize dangerous or even fatal consequences.

For correct interpretation of liver function tests in hepatic disease, it is of utmost importance to consider the bearing which the probable type and extent of the pathological process will have on any given test. Early damage to the liver may cause irritation and hyperfunction, instead of hypofunction to any test. Vigorous regeneration of hepatic parenchyma during convalescence from acute diseases, or in remissions of chronic ones, is likely to mask the extent of involvement when

Fig. 5

Fig. 5. (Case No. 72, Table 1). Liver from a patient with Banti's syndrome. The section shows perilobular fibrosis. X 100.

Fig. 6. (Case No. 252, Table 1). Liver from a patient with thrombosis of the portal vein. The section shows irregular zones of scar tissue scattered throughout the liver. X 100.

Fig. 7. (Case No. 58, Table 1). Liver from a patient with biliary cirrhosis. The section shows extensive portal scarring with bile-duct proliferation. X 100.

a metabolic test is used. Under the same conditions, due to a lag in the re-establishment of proper biliary drainage, the degree of hepatic insufficiency will be exaggerated if an excretion test is employed. Obstruction of the common bile-duct interferes immediately with tests of excretion, and after about a week begins to influence adversely metabolic tests by causing genuine parenchymatous damage. All liver function tests are much more responsive to diffuse involvement of the whole liver, even when slight, than to complete destruction of considerable portions of this organ if the remaining hepatic tissue is normal. Illustrations of this are found in patients with abscesses, cysts, and tumors which do not involve large bile-ducts. This peculiarity is explained not only by the extraordinary capacity of the liver to regenerate its substance, but also by the fact that, much like renal glomeruli, some of its functional units are normally resting and can be mobilized in case of necessity.

It is evident that extrahepatic conditions which may cause secondary insufficiency of the liver must be taken into consideration when a patient is investigated for the presence or degree of a primary hepatic disease. This, as can be seen from our data, is the greatest potential source of error, since the number of negative tests in the presence of hepatic disease is small. Dye excretion tests are influenced by the condition of the reticulo-endothelial system. The changes in the excretion of Rose Bengal caused by splenectomy and splenomegaly are a case in point. Most metabolic functional tests depend, in addition to the amount and state of hepatic parenchyma, on the activity of other organs concerned with the particular phase of metabolism. This is especially evident when various carbohydrate tolerance tests are utilized. An instance of this kind is the invalidity of the modified glucose tolerance test in hyperinsulinism.

In regard to quantitative measurement of hepatic insufficiency by liver function test, it is our opinion that the terms "slight," "moderate," and "advanced" represent the limits of accuracy. Finer distinctions, except perhaps in following the progress of the same patient, are not justified.

In the choice of a liver function test, it is well to consider that the liver possesses a number of different

functions, and that it should not be extremely difficult to work out a set of conditions under which the efficiency of one of these functions can be put to test. Consequently, it is reasonable to expect that almost any of the more commonly employed liver function tests would be useful clinically. On the other hand, there is little basis for hope that such tests, present or future\*, will prove to be free from the enumerated limitations. For this reason, it is wise in most cases not to rely exclusively on a single test, but to select one excretion and one metabolic test, and to work with them until sufficient familiarity is acquired to know what can be expected from each. Since, under ordinary physiological conditions, the amount of functioning tissue in the liver is constantly changing, tests which determine hepatic capacity during periods of induced maximum activity, are to be preferred. Tests of this type impose a "load" on the liver, as distinguished from tests which measure a normal metabolite.

In our own work, the Rose Bengal test has proven itself to be a simple, inexpensive and satisfactory excretion test. The modified glucose tolerance test, while more time-consuming and more expensive, has rendered good services as a supplementary metabolic test.

We feel that if the proper uses and inherent limitations of liver function tests were more often stressed in the literature, fewer physicians would see their exaggerated hopes disappointed, and the study of hepatic function for clinical purposes would soon settle into its proper place in medicine.

\*There is reason to believe that roentgenological visualization of the liver by means of thorium salts, if shown to be safe, will to a large extent, replace liver function tests in the diagnosis of many diseases of the liver, just as the gastro-intestinal series has limited the scope of gastric analysis. This is due to the fact that physiological tests of hepatic function measure the performance of the liver as a whole, whereas visualization of opaque salts incorporated in the Kupffer cells reveals localized destruction of even relatively small areas of parenchyma.

VIRGIL H. MOON.

*"Experimental Cirrhosis in Relation to Human Cirrhosis" General Review—Arch. Path. 18: 381-421, Sept., 1934.*

The very extensive literature upon experimental portal cirrhosis is reviewed by the author. He, as well as many other workers in this field, emphasize the fact that destruction of the lobular, architectural pattern of the liver is the most characteristic feature of portal cirrhosis in man. The author, therefore, insists upon this definite loss of lobular architecture as the essential differential criterion in determining whether any particular type of experimental cirrhosis simulates portal cirrhosis in man. This survey indicates that a number of agents, very diverse in character, are capable by repeated action, of causing this characteristic picture of experimental portal cirrhosis. The latter condition results from necrosis of hepatic cells, followed by regeneration of local patches or nodules of liver cells, with proliferation and subsequent contraction of fibrous tissue. In many of these cases, the characteristic obstruction of the radicles of the portal vein has been noted. The agents referred to above include various chemicals, (such as phosphorus plus alcohol, manganese chloride plus phenylhydrazin, and carbon tetrachloride), tars, foreign proteins, decomposition products of proteins, infections, immune sera, etc. Certain combinations of agents are frequently more effective in producing experimental portal cirrhosis than are the individual agents.

The belief that portal cirrhosis is caused directly by alcohol has not received experimental support. Alcohol alone is incapable of producing necrosis of the hepatic cells, and this is the essential first step in the development of a portal cirrhosis. On the other hand, there is convincing, experimental evidence to indicate that alcohol does act as a contributing, or aggravating, factor in the development of Laennec's cirrhosis, when it is combined with other agents capable of producing necrosis of liver cells. For example, when alcohol is used to supplement the effect of infection, phosphorus, chloroform, or carbon tetrachloride, the resulting cirrhotic changes are more marked than those resulting from the latter agents alone. This is probably due to the fact that alcohol does produce degenerative changes in the liver cells, which render the cells more susceptible to necrosis by the supplementary agent employed.

The conviction that low grade infection is an important factor in the causation of cirrhosis in man has become rather general among pathologists. Experimental portal cirrhosis has been produced in animals by repeated subcutaneous injections of putrefactive bacteria. Cirrhosis has also been produced by the repeated injection of attenuated cultures of staphylococci. The importance of a low virulence of the infecting organism has been emphasized by several workers. In an epidemic of cirrhosis among cattle, resembling portal cirrhosis in man, coccoid organisms were cultured from the livers. The same organism, when injected into rabbits, produced marked necrosis of the liver cells with early death of the animals before cirrhotic changes could occur.

There is also evidence that metabolic disturbances may be important contributing factors in the development of cirrhosis. In this connection, there is considerable evidence to suggest that hyperthyroidism may contribute to the development of cirrhosis by producing a low glycogen content of the liver. It is known that livers with a low glycogen content do have an increased susceptibility to injury.

In conclusion, the author feels that "A survey of experimental and clinical studies on cirrhosis convinces one that no single causative factor is responsible. Cirrhosis is synonymous with chronic, progressive hepatitis. Its etiology will be found to be as variable as are the agents which, singly or in combinations, may cause chronic, diffuse, progressive inflammation of the liver".

MACLAGAN, N. F.

*The Test-Meal in the Diagnosis of Gastric Disease. Lancet, 227, Sept. 1, 1934, 471-475.*

The present paper gives the results of an attempt to compare the different types of test-meal now in use, and to assess the value of each on the basis of some of the statistics which recently have been published.

All recent papers have been confined to a tabulation of the degree of acidity in the normal and diseased stomach and it is on this basis that the comparison is made. Working out the statistical probabilities from the percentage acidities in Marks' and Kantor's series of 1800 cases given the Ewald test meal no diagnostic information is gained if the question is one of peptic ulcer and similarly if the diagnosis rests between peptic ulcer and gastric carcinoma. If the question is simply one of malignancy 23.5 per cent instead of the real 22.5 per cent of cases will be diagnosed as gastric cancers, that is in the presence of achlorhydria. In applying the same methods to the same cases but using the figures obtained from Koyihar's series of 450 cases of fractional analysis the same results are gained. When however these methods are applied to Poland's series of 988 cases of histamine tests the results much more information is gained. Histamine gives useful information in 14.9 per cent of cases of doubtful peptic ulcer. It is of no use as a means of discriminating between peptic ulcer and gastric cancer. It gives useful information in 78.5 per cent of cases of doubtful carcinoma of the stomach.

John J. Day, Montreal.

FRIEDENWALD, JULIUS AND FELDMAN, MAURICE.

*The Unstable or Irritable Duodenum: Clinical Observations in One Hundred Cases. Journal of the A. M. A., 103:2007, Dec. 29, 1934.*

The unstable or irritable duodenum, like the unstable colon, results from neuromuscular imbalance.

Disturbed duodenal motility may result from mechanical, chemical, allergic, nervous or reflex causes.

Males predominate in the group of cases studied.

The symptoms may simulate duodenitis, duodenal ulcer, cholecystitis, appendicitis or other abdominal disorders. Abdominal pain is unusual. The bowels are constipated. Symptoms occur in attacks with interval periods of good health.

Diagnosis is suggested by the history of headache, dizziness, insomnia and exhaustion in a high strung individual. The gastric analysis may reveal a hyperchlorhydria. The roentgen evidence obtained by fluoroscopy of the irritable bulb is increased motility, transient irregularities and fibrillation noted along the borders, transient spasm, tenderness over the duodenum and absence of ulcer filling defect.

Treatment is based on the use of an acid free bland diet of high caloric content. Absolute rest in bed is advocated in the beginning. When hyperchlorhydria is present, alkalies should be used. Belladonna and atropine are useful to allay spasm.

Francis D. Murphy, Milwaukee.

## SECTION II—*Experimental Physiology*

### Decompression of the Obstructed Biliary System in the Cat\* II. Serum Bilirubin Concentration and Bromsulphalein Retention

By

ABRAHAM CANTAROW, M.D.

HAROLD L. STEWART, M.D.

and

STANLEY G. McCOOL, M.D.

PHILADELPHIA, PENNSYLVANIA

THE materials and methods employed in this study have been described previously (1, 2). Estimations of serum bilirubin concentration and bromsulphalein retention were made at varying intervals during total stasis and following removal of the ligature on the common duct. Bromsulphalein was injected in the dosage of 2 mg. per kilogram of body weight and the figures reported represent the degree of retention at the end of 30 minutes. Serum bilirubin was determined by the Van den Bergh method as modified by Thannhauser and Anderson. All animals were excluded from the present report in which any complicating factor was present. Sections of liver were removed at the time of operation for removal of the ligature on the common duct for the purpose of comparing the histologic features of the liver of stasis with those of the liver of decompression in individual cases. The data presented herewith, therefore, represent the changes in serum bilirubin concentration and bromsulphalein retention during uncomplicated total bile stasis and uncomplicated subsequent decompression of the biliary system in 17 cats, in 11 of which cholecystectomy had been performed at the time of ligation of the common duct.

#### EXPERIMENTAL OBSERVATIONS

##### *Serum Bilirubin Concentration:*

The serum bilirubin values during stasis and decompression are presented in detail in Table 1. Although there was marked individual variation in the degree of bilirubinemia during stasis, the findings in the animals with gallbladders and patent cystic ducts did not differ essentially from those in which cholecystectomy or cystic duct ligation had been performed. The direct Van den Bergh reaction was positive in every case in which bilirubin could be detected in the blood serum. The concentration tended to reach a maximum between the end of the first and the middle of the second week of stasis.

The following changes in serum bilirubin occurred after removal of the ligature on the common duct:

1. Marked decrease at the end of 24 hours: Cats 63, 87, 121, 122, 125, 128, 129, 131, 132, 143 and 147.
2. Gradual decrease (24-96 hours): Cats 82, 116 and 152.
3. Primary decrease and secondary increase: Cats 63 and 77.
4. Primary increase and secondary decrease: Cat 72.
5. Unchanged: Cat 144.

##### *Bromsulphalein Retention:*

The data regarding the degree of dye retention during stasis and decompression are presented in detail in Table 1. The variation in this factor was even more marked than in the serum bilirubin concentration. An absence of bromsulphalein retention was observed as late as the 15th day of stasis (Cat 128) while 100 per cent retention was noted as early as 24 hours after ligation of the common duct (Cat 87).

The following changes occurred after removal of the ligature from the common duct:

1. Marked decrease at the end of 24 hours: Cats 63, 87, 121, 122, 125, 129, 132, 143, 147 and 152.
2. Gradual decrease (24-96 hours): Cats 82 and 116.
3. Primary decrease and secondary increase: Cats 63 and 125.
4. Increase: Cat 77.
5. Unchanged (no retention): Cats 128, 131 and 144.

#### DISCUSSION

##### *Serum Bilirubin Concentration:*

Cantarow and Stewart (1) have pointed out the fact that no morphological basis can be demonstrated for the marked degree of individual variation in serum bilirubin concentration during total bile stasis. No correlation could be established between the degree of bilirubinemia and the occurrence or extent of regressive and regenerative changes in individual cases. Their observations seemed to indicate that there is no demonstrable correlation between the structural changes in the liver and bile ducts and the variability

\*From the Laboratory of Biochemistry, Jefferson Hospital, the Laboratories of Pathology, Jefferson Medical College and Hospital and the Jefferson Hospital Tumor Clinic.  
Submitted January 26, 1935.

in serum bilirubin concentration during the period of total stasis. It was also noted, as in the present series, that after ligation of the common bile duct the rather rapid initial rise in serum bilirubin is followed by a fall to a comparatively low level. The possible dependence of this phenomenon upon anemia, diminished activity of hemoglobin regeneration and suppression of bile acid synthesis was discussed in a previous communication (1).

Clinical observations upon patients following operative or spontaneous relief of common duct obstruction indicate that in the majority of cases which terminate favorably the serum bilirubin concentration falls to normal promptly or within a relatively short time. Similar findings were reported by Snell, Greene and Rowntree (3) and by Armstrong (4) in a few observations made upon dogs. In the present series, a marked decrease in the degree of bilirubinemia occurred within 24 hours in 11 animals following relief of total stasis of 1-16 days' duration. In these cases (Cats 63, 87, 121, 122, 125, 128, 129, 131, 132, 143 and 147) the architectural distortion which constituted one of the most prominent features of the liver of decompression was present to only a relatively slight degree. Only two of these animals (63 and 131) fell into the group in which stasis had existed for 6-10 days, the group in which the subsequent disturbance of architectural pattern appeared to be most marked. Furthermore, in one of these (121) this feature was not pronounced and in the other (63) the serum bilirubin, which decreased during the first 24 hours of decompression, exhibited a secondary increase during the second day, associated apparently with complete suppression of bile secretion. There was much less uniformity in the extent of regressive changes in the hepatic parenchyma in this group. In three instances (87, 121, 132) there was a distinct diminution in the extent of sporadic and focal necrosis and improvement in the appearance of the subcapsular zone (after 7 days decompression in Cat 87); in two cases (131 and 143) there were definitely increased degeneration and necrosis generally throughout the parenchyma, being very marked in Cat 131, in which only about 20 per cent of the hepatic cell nuclei were visible. In two additional cases (128 and 147) degenerative changes in the subcapsular area were increased although the remainder of the parenchyma seemed to be recovering from the effects of stasis. Although some evidence of hepatic cell regeneration, including mitotic figures, binucleation, nuclear hyperchromasia and the presence of characteristically new hepatic cells, was noted in every animal in this particular group, these features were extremely inconstant and variable in degree, bearing no apparent relation to the clinical condition of the animal nor to the extent of fall in serum bilirubin concentration. The same was true of pigmentation and changes in the Kupffer cells and proliferated bile ducts. Bile was present in the intestine and ducts in each case, was of thin consistency and varied in color from light brown to dark green.

In Cats 63 and 77, a primary fall in serum bilirubin was followed by a rise during the second day of decompression. In the latter case the final value, 2.24 mg. per 100 cc., exceeded any obtained in that animal during stasis. There was only slight architectural distortion and relatively slight regression of the proliferated bile ducts which were exceedingly numerous, practically completely surrounding each lobule. Hy-

aline necrosis was rather extensive. Although mitotic figures were scarce there was other evidence of regeneration of hepatic cells, certainly not less than in animals in which the serum bilirubin fell promptly following relief of obstruction. The bile ducts were patent and thin brown bile was present in the intestine and ducts. In Cat 63, in which there was apparently complete suppression of bile secretion, there was a definite increase in the degree and extent of the regressive changes in the hepatic cells and also marked architectural distortion. On the other hand, mitotic figures were exceedingly numerous and there were other striking indications of active hepatic cell regeneration. The secondary increase in the degree of bilirubinemia in this case, however, may have been dependent in part upon the fact that thrombosis had occurred in several branches of the portal vein.

In the three cases in which the serum bilirubin diminished gradually (Cats 82, 116 and 152), the degree of architectural disruption varied from slight (116) to moderate, and degenerative changes in the hepatic cells were equally variable. A marked feature in Cat 116 was the extreme degree of disarrangement, loosening and edema of the connective tissue about the larger intrahepatic bile ducts. Active regeneration of hepatic cells was noted in each instance, being particularly marked in Cat 82, in which 2 mitotic figures could frequently be seen in single high-power fields; thrombosis of branches of the portal vein were present in this case.

In Cat 144, in which no change occurred in the serum bilirubin concentration (0.0 mg.), the liver showed increased degeneration and necrosis, moderate disruption of architectural pattern and slight evidence of hepatic cell regeneration, no mitotic figures being noted. In Cat 72, which exhibited a primary increase in bilirubinemia and a secondary fall, morphological studies unfortunately were not made at the time of the increase in serum bilirubin.

These detailed histologic studies fail to establish any consistent correlation between the very striking morphological features of the liver of decompression and the variable changes which occurred in the serum bilirubin concentration following relief of biliary stasis. The rapidity of fall of the serum bilirubin and the development of increased bilirubinemia apparently were independent of and entirely unrelated to the extent of architectural, regressive or regenerative changes in the hepatic parenchyma and to changes in the bile ducts. Changes in the serum bilirubin were also unrelated to changes in the lipid content of the hepatic and Kupffer cells which was studied in detail and which will be described in a subsequent report.

#### *Bromsulphalein Retention:*

Cantarow and Stewart (1) found that during complete bile stasis in cats there was no apparent relationship between the degree of bromsulphalein retention and the morphological changes in the liver and bile ducts, either in individual cases or in the group of animals as a whole. The range of individual variation in the degree of dye retention was even more marked than in that of bilirubinemia and was not consistently related to the duration of stasis. The data presented in Table 1 illustrate the lack of correlation between the degree of bilirubinemia and of bromsulphalein retention during the period of stasis in the animals included in the present study. Cantarow and Stewart (1) discussed the possible causes of the vari-

ability of dye retention which may be dependent upon several variable factors, including destruction, storage or extrahepatic elimination of the dye.

Clinical observations upon patients with obstructive hyperbilirubinemia indicate that following relief of the obstruction to the flow of bile, the degree of dye retention, although diminishing, usually persists for a variable period of time after the serum bilirubin concentration has returned to normal. This has been attributed to the residual hepatitis which is present in nearly all individuals who have suffered from biliary obstruction for an extended period. In a few observations upon dogs, Snell, Greene and Rowntree (3) found that bilirubinemia and dye retention decreased simultaneously following the re-establishment of bile flow and they concluded that the two phenomena are distinctly related.

In the present series of animals, a marked decrease in the degree of bromsulphalein retention was present at the end of 24 hours following relief of obstruction in 10 instances (Cats 63, 87, 121, 122, 125, 129, 132, 143, 147 and 152), after stasis of 1-16 days duration. With a single exception (152), this was associated with a corresponding fall in the serum bilirubin concentration. In the latter case (152) there was no demonstrable morphological basis for this discrepancy. The hepatic lesions and the changes in the Kupffer

cells differed in no essential respect from those present in the other animals in this group. In Cat 63 the primary decrease in the degree of dye retention and bilirubinemia was followed by a secondary increase in both factors. At the time of this increase (48 hours decompression) the only unusual morphological finding was thrombosis of some of the branches of the portal vein, although both regressive and regenerative changes in the hepatic parenchyma were more pronounced than during stasis. No consistent morphological changes were associated with the prompt decrease in dye retention exhibited by this group of animals. The regressive, regenerative, vascular and ductal lesions characteristic of the liver of decompression varied considerably and bore no demonstrable relation to the uniform functional findings in these cases.

A relatively gradual diminution in the degree of dye retention was noted in 2 instances (Cats 82 and 116). In Cat 82, which had appeared quite toxic since the removal of the ligature on the common duct, rather marked regressive changes were associated with evidences of extremely active regeneration of hepatic cells, extensive vacuolization of the bile duct epithelium, marked pigmentation of both hepatic and Kupffer cells and thrombosis of branches of the portal vein, with infarction. In Cat 116 there was extreme

†Cholecystectomy.

disarrangement, loosening and edema of the connective tissue about the larger intrahepatic bile ducts. Otherwise, the liver and ducts presented no lesions which differed in any essential respect from those noted in cases in which the degree of dye retention fell promptly following restoration of bile flow.

In Cat 63, a primary decrease in bromsulphalein retention from 70 per cent to 25 per cent (24 hours) was followed by a secondary increase to 100 per cent at the end of 48 hours of decompression. The liver at this time showed marked architectural distortion, increased degeneration and necrosis and evidences of extremely active hepatic cell regeneration. There were thrombosis of several branches of the portal vein and apparently complete suppression of bile secretion, with a slight increase in serum bilirubin and no pigmented bile in the duct system. A sustained increase in the degree of dye retention, from 55 per cent to 100 per cent after 24 and 48 hours of decompression, occurred in Cat 77, accompanied by an increase in the serum bilirubin concentration. With the exception of rather extensive hyaline necrosis, regressive changes were not marked and hepatic cell regeneration was only moderately active. There were only slight architectural distortion and marked proliferation of the smaller bile ducts. No dye retention was noted during the period of decompression in Cats 128, 131 and 144, in which no retention had been present during stasis. Cat 131 showed a very marked degree of sporadic necrosis, only about 20 per cent of the hepatic cell nuclei being visible in histologic sections. Regressive changes were also more extensive than during stasis in Cat 144. Architectural distortion varied considerably as did hepatic cell regeneration. In Cat 128 there was an extreme degree of Kupffer cell vacuolization (fat).

On the basis of these observations, it seems clear that the degree of bromsulphalein retention diminishes rapidly in the majority of cases following the re-establishment of bile flow. In most cases in which it diminished more gradually or actually increased the

morphological changes in the liver differed in no essential respect from those in which it fell promptly. Thrombosis of branches of the portal vein may have been responsible, in part at least, for the findings in Cats 63 and 82. In general, however, it appears that similar changes in dye retention may occur during biliary decompression in animals with widely differing morphological changes in the liver. On the other hand, variable functional findings may be obtained in animals in which histological examination of the liver reveals no significant morphological differences. The same applies to the lipid content of the hepatic and Kupffer cells which will be described in a subsequent report. It is also of interest that, with a single exception (Cat 77), the changes in the degree of bromsulphalein retention approximately paralleled those in bilirubinemia during decompression. This is in sharp contrast to the frequent lack of parallelism of these two factors during total stasis.

#### SUMMARY

1. No consistent correlation could be established between the striking morphological features of the liver of decompression and the changes which occurred in the serum bilirubin concentration following relief of biliary stasis.

2. In the great majority of cases, the serum bilirubin fell promptly following relief of obstruction.

3. In contrast to the findings during total stasis, during decompression changes in the degree of dye retention generally paralleled the changes in bilirubinemia.

4. No consistent correlation could be established between morphological changes and the changes in the degree of bromsulphalein retention during the period of decompression.

## ABSTRACTS

McGAUGHAN, J.M., M.D.

*The Value of Estimation of the Amylase of the Blood in the Diagnosis of Suspected Pancreatic Disease. S. G. and O., Volume 59, No. 4, Oct., 1934, pp. 598-610.*

In this article a review of the literature on this subject is made and a series of experiments involving various pathological conditions of the pancreas is reported.

In a series of fifteen apparently healthy dogs, blood amylase averaged 24.6 units, the lowest reading obtained was 15 units and the highest was 44.4 units.

These experiments showed that obstruction to the outflow of pancreatic juice which occasioned various degrees

of pancreatitis showed rises in blood diastase values above normal within a very few hours, the maximal rise being reached in about 72 hours and being sustained for from eight to fifteen days. The height of the rise is directly proportional to the degree of occlusion of the pancreatic duct or to the extent of parenchyma involved in the inflammatory process. Following this initial rise in the blood diastase after about two weeks the curve gradually returned to normal.

The author feels that this test may be very valuable in the detection of pancreatic disease, but points out that its value lies in the early stages of the disease.

N. W. Swinton, Boston.

## SECTION III—Nutrition

### Clinical Evidence of Fifty So-Called Gastrointestinal Diseases Which Really Are Caused by Food Allergy With Discussion of Their Treatment\*

By

JOSEF S. SMUL, M.D.  
NEW YORK CITY, NEW YORK

IN order to present clinical evidence of gastrointestinal food allergy we take as our problem the patient who is frequently "conscious" of his digestive tract. We contend, and will endeavor to prove, that the vast majority of these patients are born with an alimentary tract which is "sensitive" to certain normal foods, or to certain normal cleavage products, derived during normal digestion or to both. (1) This phenomenon is known as "allergy" and is responsible for about fifty clinical syndromes which now are described as individual gastrointestinal "diseases" in all standard text books.

Three sources must be examined in order to find the cause of all forms of distress of the alimentary tract. For this reason, it is best to separate the diseases causing distress in the alimentary tract, according to the sources of the *etiologic irritants*, into three groups:

*Alimentary Group A.* represents that gastrointestinal malfunction which is caused by irritants whose source is *outside* the body, as happens with allergic foods. This affection with its protean symptomatology, can be prevented or controlled by eliminating the allergic foods from the daily diet.

*Alimentary Group B.* represents those gastrointestinal "diseases" which are caused by irritants whose source is *in* the alimentary tract: Diverticula, Carcinoma, Appendicitis, Acute Bacterial Gastrointestinal Intoxication, Bacillary Dysenteric Colitis, Amebic Dysenteric Colitis, Tuberculous Enterocolitis, Amyloid Disease, Chronic Plumbism, Megacolon, Intestinal Parasites.

*Alimentary Group C.* represents those gastrointestinal diseases which are caused by irritants whose source is *outside* the alimentary tract, but *in* the body: Diseases of the Liver and Gall Bladder (tumors, cysts, amyloid); Diseases of the Pancreas (tumors, cysts); Diseases of the Nervous System (migraine, lues, tumors, neurasthenia and other nervous and psychic derangements); Diseases of the Blood (pernicious anemia, leukemia, lymphatic anemia, splenic anemia); Diseases of the Endocrine Glands (hyperthyroidism,

diabetes, hypoparathyroidism); Diseases of the Heart (especially those accompanied by decompensation); Diseases of the Lungs (tuberculosis, pleurisy, tumors); Diseases of the Kidneys (nephritis, pyelitis, tumors, cysts, stones); Diseases of the Genital Organs (tumors, cysts, inflammation, ectopic); Hypertension.

#### ALIMENTARY GROUP A.

Since we are mainly interested in the fifty so-called alimentary "diseases" described in standard text books with only theories or suggestions as to cause and cure, we will consider first *Alimentary Group A*. In conformity with our suggested nomenclature personally we call the digestive disorder embracing what now are fifty separately described diseases, "Alimentallergy".

We will now endeavor:

(1) To show the etiology of the generally considered fifty gastrointestinal "diseases". (2) To induce proof that all these fifty separately described "diseases" are only different groups of symptoms of one disease, "Alimentallergy". (3) To show a method of preventing and neutralizing the evil effects of this malfunction. (4) To show the discovery of a method which obviates the customary routine of testing each patient for each allergic food. (5) To show a method whereby all cathartics and enemas may be omitted in the treatment of this affection, from which suffer nine-tenths of all who require artificially produced bowel evacuations.

#### DEFINITION

Alimentallergy is a condition of the gastrointestinal tract, characterized by an *inborn* sensitiveness to certain normal foods, or to certain normal digestion cleavage-products formed during normal digestion or to both.

#### ETIOLOGY

The cause of this disturbance is an inborn sensitiveness of the alimentary tracts of these patients either to certain normal foods, or to certain cleavage products derived during normal digestion, or to both. In 1922, backed by an extensive experience with gastrointestinal patients, sufficient reasons appeared to warrant suspicion that "food allergy" was the cause of their distress. Many of the following observations led

\*Read (abbreviated) before the New York Physicians-Yorkville Med. Soc. in New York.  
Submitted December 4, 1934.

1. Smul, Josef S.: Gastrointestinal Diseases and Food Allergy, *Med. Jour. and Record*, January 20, 1932.

to this conclusion. It should here be emphasized that although not all the allergic characteristics enumerated below readily can be demonstrated in each of the fifty "diseases" constituting alimentallergy, enough can be demonstrated to prove the allergic nature of each.

### PROOF OF THE ALLERGIC NATURE OF ALIMENTALLERGY

#### 1. *Sudden Onset And Sudden Cessation Of Distress.*

We have been impressed by the sudden onset and sudden cessation of the distress of this affection. Such features are characteristic of anaphylactic conditions. The attack is apt to appear suddenly, last for some time, disappear, and then reappear after an appreciable period of comfort. Most patients are able to assign a cause for the attack. Since they were able to tell approximately when an attack began, they would recall what, to them, produced the upset. One would assign the cause to food eaten at a banquet, the other at a funeral; one would blame the restaurant, the other would blame the cook; one would attribute it to solids, the other to liquids.

If we examined these supposed causes, we would find that the same patients really had been to many banquets and to many funerals without experiencing attacks. Often they had eaten in the same restaurants, or had had the same cook without experiencing any distress. They had eaten the same solids and the same liquids without any ill effects. Indeed, the similarity of these statements to those made by patients with asthma is striking: the asthma patient slept in the same bed and used the same clothing or food for a long time without any trouble; then, suddenly, he developed an attack of asthma. In these cases the explanation offered as the variable factor was a "cold". The patient always could tell *when* the cold came, although he could not tell *how* it came. Nevertheless, he was satisfied to call it a "cold". Then came the knowledge of allergy to explain the cause. Since the liability to an attack depends upon a certain degree of sensitiveness, the patient was able to tolerate the allergic materials during the desensitized period. As soon as his sensitiveness reached a certain degree of excitability, he developed an "attack", should he come into contact with the allergic substance.

Exactly the same condition would seem to operate in the gastrointestinal tract. The patient may eat the allergic foods during the "desensitized" period without any trouble. As soon as he becomes "sensitive" he experiences an attack of alimentary distress, if he eats the allergic materials.

2. *Sensitiveness to Small Amounts of Certain Commonly Used Foods.* We have noticed that some of our patients were, at times, sensitive to such small amounts of certain commonly used foods that the consequences could only be explained by allergy.

*Practical Method of Testing Food Sensitiveness.* From the daily foods, a certain number was selected and from this number our gastrointestinal patients were allowed to eat and drink of them as much as they liked. Also they could choose their own time and manner of eating. But they were not allowed to take any other food and they were compelled to eat of each food allowed at least once a day. If they had no distress they were directed to return for observation in a week. If they were distressed they were asked to report at the end of the day. If the patient reported that he had distress, we endeavored to deduce from

the relation in time between the ingestion of the food and the appearance of pain or discomfort which of the food materials was most likely to cause his distress. The patient was instructed to omit the questionable food from his diet, and advised to eat more of the remaining foods. Occasionally the original selection of prescribed foods in the case became exhausted and a new list had to be prescribed. When the patient had been comfortable for some time, he was retested on each food which had been removed from the original group, to make certain which substance it was which he could not tolerate. In that way the allergic material was discovered. The knowledge thus acquired, enabled us to precipitate an allergic attack or prevent one at will.

The facts stated above also proved that it was not the *amount* of food, nor the *time* or *manner* of eating, which disturbed the patient. The patient who became deathly sick from a spoonful of a certain food, was able to tolerate twenty times as much of another food. The same disturbing food might be taken in quantities twenty times as large by a non-sensitive person, without any ill effects.

(3) *Gastric Acidity.* For many years it was believed that acid, which is a constituent of the normal gastric secretion, was the cause of all forms of gastric disturbance, especially the periodic pain which occurs with or without peptic ulcer. Lately, it has been found that the same type of periodic pain also may exist in persons with anacidity, with achylia or after gastrectomy. Furthermore, fractional examinations of the gastric contents show that the pain does not correspond with the period of highest acidity. Also, it is known that when the stomach contents artificially are evacuated or when the patient vomits at the time of the pain, the pain ceases at once, irrespective of whether or not the stomach contents have an acid reaction.

The examination of the gastric contents thus obtained, reveals normal food and normal cleavage products occurring in the process of normal digestion. Yet, on reintroducing these normal contents to the stomach of the same patient, the previous pain soon recurs.

On the basis of the above observations, we feel justified in concluding that the periodic pain is due to certain normal foods, *when it occurs soon after ingestion*. However, if the pain is *delayed*, it would seem to be due to certain normal cleavage products appearing at that time. Both substances may act as allergins in the stomach.

It can be said in regard to gastric acid, that the allergic substance seems more active in its presence than in its absence.

The normal gastric contents found in "alimentallergy" also explain why many patients suffering distress from it for many years, remain well nourished. The only time these patients show a lack of nourishment is when they eat little because they dread distress, when they vomit much of the food they ingest or when they suffer from diarrhea.

(4) *Spasm.* After the abandonment of the acid theory, the spasm theory was advanced to explain the abdominal pain.

Dr. Hitzenberger (2), at the Wenkebach Clinic of Vienna, instructed his nurses to notify him immedi-

2. Hitzenberger, K.: Personal communication at the Wenkebach Clinic of Vienna, 1930.

ately when a gastric patient complained of pain. He had everything prepared, and in a few minutes the patient was being fluoroscoped. He observed no different contractions of the stomach or the duodenum than at the previous examination when the patient had been experiencing no pain, even though the pain persisted during the examination being discussed. Dr. Hitzenger continued these experiments for a considerable period, and concluded that there was no relation between the periodic pain of the stomach or duodenum and any form of spasm. However, on removing the gastric contents from the stomach, as described above under "gastric acidity", the pain ceased.

Thus, there would seem some ground for believing that the only logical explanation is, that the gastric pain is due to certain normal foods or to certain normal cleavage products, which act as allergic substances in the stomach or in the intestines.

(5) *Trauma*. When the traumatic theory of gastrointestinal ulcers was advanced, many experiments had been made in the effort to produce chronic ulcers in animals, similar to those found in man, but without success. The animal's gastric mucosa was damaged, the gastric hydrochloric acid and pepsin were there, but the lesions healed. The explanation would appear to be that the stomachs of the animals are not sensitive to the ingested food. In man, the situation is different. Apparently, a large proportion of humans are born with alimentary tracts which are "sensitive" to certain normal foods which are universally used in the daily diet. Seemingly, it is the *repeated ingestion* of these foods by those with sensitive alimentary tracts which causes and maintains peptic ulcer in man. Alkalies and atropine diminish the allergic activity and thereby produce an amelioration, but they do not remove the cause. However, on withholding from the daily diet those foods which we found to be allergic and feeding the patient on the foods we found to be non-allergic, gastrointestinal ulcers will not develop, or, when present, will heal and not recur, unless the patient resumes the ingestion of the allergic foods.

(6) *Intestinal "Autointoxication"*. There is a group of symptoms causing abdominal as well as general disturbances, which is classed under the term "intestinal autointoxication". This autointoxication is supposed to be produced either by the intestinal mucosa, by improper cleavage of protein during its digestion, or by the usual intestinal bacteria (3). Formerly, it was assumed that this condition occurred especially in those who experienced infrequent bowel movements, and it was taught that assuring regular evacuations would prevent or cure autointoxication. Recently, the contention has been that the autointoxication symptom-complex is more likely to occur when diarrhea is present. The fact is, that those who do not suffer from food allergy do not develop these symptoms whether their bowels move once in five days or five times in one day. But it is a fact also that, if those who *suffer from food allergy* move their bowels more than once a day for any reason, or have a desire to move them more than once a day, invariably they will develop the group of symptoms known as "autointoxication". We observed that if the sensitive patient adhered to the diet rules of food allergy hereinafter described, this group of symptoms does not develop.

In our opinion, what is called "autointoxication" is a fiction.

(7) *Infection*. It is significant that, as far back as infection has been known, many syndromes referable to the digestive system, included in this group, have been laid directly or indirectly at its door. Yet all these claims still are being debated. The present consensus of opinion is that although infection is, in itself, not a primary etiologic factor, it is believed that it may be a contributory cause, even if no positive proof exists to substantiate this suspicion. With so many bacteria always existing in the alimentary canal and the easy accessibility of organisms that enter with the food, it becomes possible to see how infection would suggest itself as a logical causative agent in disease production, but, so far, no one has proved the true relationship, and certain available facts contradict it. The most that can be conceded in this connection is that *after* allergic foods produce damage to the alimentary tract mucosa, certain bacteria then may become virulent, or a group of organisms which ordinarily cannot exist then may enter and contribute to the damage. Evidence to substantiate the last statement may be gathered from the observation that, in some severe cases of colon allergy, the treatment for food allergy is not adequate and autogenous vaccines prepared from bacteria are required. However, in order to secure continuous good results affected patients must adhere to such dietetic restrictions demanded in food allergy, as will be mentioned later.

(8) *Allergic Substances Select Specific Sites*. We observed that allergic substances select not only particular organs or tissues, but also particular sites in the tissue or organ of each individual, which tissue, when "sensitive", always reacts in the same peculiar way.

All are familiar with eczema appearing, disappearing and reappearing in certain individuals, say, on one cheek, behind one ear, over one thigh, or between two fingers on one hand, while the remainder of the skin remains normal. We are also familiar with the particular site the allergic material selects in asthma, or in hay fever. The resulting damage depends upon the amount and duration of the allergic substance on one hand, and upon the degree of sensitiveness and the reaction of the particular tissue in each individual, on the other. It is admissible that an eczema-like lesion situated in the mucous membrane of the stomach or the intestines might become manifest as an ulcer.

Under this conception one logically may explain: (1) the abnormal gastrointestinal motility causing retention, constipation or diarrhea; (2) the alimentary distress of a patient without evident pathology, as in what is now called a simple dyspepsia or a gastric neurosis; (3) the pathology of a hypertrophic or an atrophic stomach or intestine; (4) gastric vascular spasm; and (5) the production, maintenance and selection of a particular site of an ulcer on the lesser curvature of the stomach or the duodenum, including the marked infiltration of eosinophiles, so characteristic of allergic conditions.

(9) *Duke's (4) Proof Of Allergic Cause*. To prove that our position, (as will be emphasized in discussing treatment), fulfills all the requirements necessary to

3. Hewlett, Albion Walter: *Pathological Physiology of Internal Medicine*, D. Appleton and Co., 1928, pp. 204-205.

4. Duke, William W.: *Allergy: Asthma; Hay Fever; Urticaria and Allied Manifestations of Reactions*. The C. V. Mosby Co. 1925, p. 74.

establish the allergic nature of the etiology of affections being considered, the four criteria suggested by Duke are introduced, namely:

(a) If the patient is removed from contact with the suspected substance, he is relieved of symptoms.

(b) If we re-introduce the suspected substance when the patient is well, he has a recurrence of the symptoms *c. g.* as when the patient returns to his previous diet.

(c) If the patient persists in supplying the allergic substances, the tissues will become "exhausted" and cease to react to the suspected substance; this is demonstrated by what are called "spontaneous remissions".

(d) If small amounts of the allergic substances slowly are introduced, the symptoms will cease and a "tolerance" will develop, (see treatment *infra*).

This method of applying directly the *suspected* substance to the *suspected* tissues is called the "direct method" of proving that allergy is the cause, should a reaction follow. It is reliable and is to be preferred to the less reliable "indirect method"; the latter should only be used in cases where the direct method is impractical or impossible.

In inhalatory allergy, it is difficult to apply a definite amount of the suspected inhalent to the affected tissues. Furthermore, serious consequences may follow the use of the direct method in the respiratory tract. Therefore the indirect method, namely *the skin test* is employed.

In gastrointestinal food allergy, the use of the direct method is not difficult. The distress which follows the direct exhibition of offending substances can be controlled readily and no serious consequences appear. Moreover, while there is a considerable relation in the sensitiveness to allergic substances between the skin and the respiratory tract, there is hardly any relationship between the skin and the alimentary tract. Hence the direct method would appear to be the only possible and reliable one to be employed in alimentary food allergy.

Of course the *degree* of sensitiveness of the alimentary tract in allergy varies as does that of the lungs in asthma, or that of the skin in angioneurotic edema. The tissues of these organs sometimes are more sensitive to the allergic substances and, at other times, less. Therefore, frequently we hear that a patient previously has had a similar attack of alimentary distress, but that he has been "cured" and has been well for some time: such a statement frequently is made with respect to all forms of allergy.

#### CLASSIFICATION

It has seemed convenient to divide alimentallergy into six forms; this grouping replaces the following fifty so called "diseases":

(1) *Irritable Alimentallergy*. This form of alimentary tract allergy has no demonstrable pathology and is known only by the distress which it produces. It accounts for the following conditions often considered as diseases: Superacidity, Supersecretion, Gastro-myxorrhoea, Bulimia, Parorexia, Gastralgokenosis, Gastralgia, Hyperesthesia, Regurgitation, *Eruclatio Nervosa*, *Vomitus Nervosus*, *Nausea Nervosa*, Cardiospasm, Pylorospasm, Pneumatosis, Peristaltic Unrest, Nervous Dyspepsia, Subacidity, Anacidity, Acoria, Anorexia, Sitophobia, Incontinence of Pylorus, Atony, Gastrectasis, Hematemesis (diapedesis), Intestinal Gas Distension, Intestinal Indigestion, Intestinal Colic,

Intestinal Hemorrhage (diapedesis), Constipation, Diarrhea, Infantile Diarrhea, Sprue.

(2) *Acute Inflammatory Alimentallergy*. This type is characterized by an acute transitory inflammation involving the mucosa and replaces the following so-called distinct affections: Acute Gastritis, Acute Enteritis, *Cholera Nostras*, Acute Colitis.

(3) *Acute Suppurative Alimentallergy*. This form of allergy is rare and ends fatally. It is characterized by an acute suppuration of the submucosa and replaces the following conditions: Suppurative Gastritis, Suppurative Enteritis.

(4) *Chronic Hypertrophic Alimentallergy*. This form is characterized by chronic hypertrophy and replaces the following so-called lesions: Chronic Hypertrophic Gastritis, Chronic Hypertrophic Enteritis, Polyposis.

(5) *Chronic Atrophic Alimentallergy*. This form is characterized by chronic atrophy and accounts for: Chronic Atrophic Gastritis, Cirrhosis of the Stomach, Chronic Atrophic Enterocolitis.

(6) *Autolytic Alimentallergy*. This form is characterized by chronic ulcers in the stomach or intestines and replaces lesions considered as disease entities: Gastroduodenal Ulcer, Intestinal Ulcers, Ulcerative Colitis.

#### NOMENCLATURE

The term "alimentallergy" indicates the cause and the site of the disease in conformity with the rules adopted by the International Medical Nomenclature Committee. It is best to omit the old terms because the "diseases", such as they are supposed to represent cannot individually be diagnosed and differentiated from one another during life, by either distinctive etiology, pathology, physical findings, chemical studies, symptoms or treatment. Therefore, the ancient terms are of neither scientific or of practical value.

#### SYMPTOMS

In spite of the fact that the tendency to each particular kind of allergy is inborn, it is characteristic of all forms of allergy that the *manifestation time* varies from the first few days after birth to any time up to the end of life and that all exhibit regressions, remissions and recurrences.

The complaints of the patient in allergic disease are: increased or decreased desire for food, bad taste in the mouth, abdominal distress, fullness in the abdomen, heartburn, eructations, regurgitation, nausea, vomiting, abdominal pain, too frequent bowel movements, inconvenient bowel movements, or blood in the vomitus or stool. Any one or several of these complaints may be present. Distress in various parts of the body may accompany these symptoms: as headache, dizziness, restlessness and fainting spells.

#### DIAGNOSIS

The diagnosis is made by the history of regressions, remissions and recurrences of the above named symptoms, the finding of peptic ulcers with the X-ray or in the rectum by the proctoscope in some patients, the cure of the patient through the mode of management to be mentioned and the previous exclusion of the diseases named in Groups B and C above mentioned.

#### PROGNOSIS

Since allergy is an inborn characteristic which it is impossible to eradicate, one is advised not to use the word "cure" in these cases. However, so long as the

patient will carry out the advice given, he should remain free from symptoms; this is the nearest to cure which it is possible to promise an allergic patient. With this limitation we can promise our patient a 100% cure.

*The causes of failure are:*

(a) The patient does not carry out the treatment properly and adequately.

(b) There exists deformity, as induration, hypertrophy, contraction or adhesions of the alimentary tract, which may have developed from pre-existing ulcers or other organic lesions.

(c) A mistake has been made in the diagnosis. In such circumstances, the cause of the alimentary disturbance is not food allergy and the case does not belong to Group A. The source of the irritant may be a type of intra-alimentary belonging to Group B, or it may be extra-alimentary but within the body, as suggested by Group C.

### TREATMENT

The treatment consists in withholding those foods to which the patient happens to be sensitive and in feeding him foods to which he is not sensitive. At the beginning of our studies, we tested each individual patient for every food, mentioned above under "etiology". However, after testing a large number and then observing them for several years, we noticed that the foods fell into common groups. These we consolidated into one group of foods allowed, called "anallergic foods", and another group prohibited, called "allergic foods". These food lists have been used for a number of years and are perfectly satisfactory. One may state that often the foods to which these patients are sensitive are not essential to life and that the variety of foods which benefits them is so great, that the daily requirements easily are satisfied. The "anallergic foods" also serve as hypo-sensitizers; the patient is obliged to eat them if he would lose his distress rapidly.

It is important to remember that gastrointestinal food allergy differs considerably from inhalatory allergy in that the allergic food easily can be eliminated from the diet and yet the patient's daily food requirements readily can be satisfied. Hence "desensitization" is of very little importance in this disease.

However, in order to "hypo-sensitize" the patient to a particular food, one begins to feed him on small quantities of that food and increase it very slowly until the maximum tolerance is reached or until the patient can tolerate a reasonable quantity.

### DIET

(a) Remove the allergic irritant by withholding the following foods:

#### *Allergic Foods*

Tea, coffee, chocolate, soup (all kinds), syrup, liqueurs, sauces, gravies, beef juice, sour milk, sour cream, malted milk, prune juice, chopped meat, anything fried, anything stewed, spices, onions, radishes, horseradish, sugar, candy, cake, ice cream, pie, pudding, jelly, zweiback, toast, rye bread, bran, oatmeal, corn, wholewheat, mushrooms, cheese, sweet potatoes, herring, catchup, pepper, beans (dried or baked), apples (raw or baked), oranges, grapes, grapefruit, strawberries, figs, dates, raisins, corn flakes, condiments, stomachics, appetizers, pimento.

Patients suffering from food allergy of the digestive system are sensitive to the above foods. None of

these foods is allowed. Other procedures not allowed are: Heat to abdomen, laxatives and enemas.

(b) Feed the patient on the following foods:

#### *Anallergic Foods*

Eggs, soft or hard boiled; fish, boiled or broiled; chicken, boiled or broiled; beef, boiled or broiled; veal, boiled or broiled; lamb, boiled or broiled; liver, boiled or broiled; oysters, raw; sweet cream; butter; chicken fat; white bread, fresh or old; farina, with butter or cream; rice, with butter or cream; noodles, with butter or cream; macaroni, with butter or cream; cream of wheat, with butter or cream; custard; lettuce; tomatoes; potatoes, boiled, baked or mashed; green peas, boiled or steamed; string beans, boiled or steamed; cauliflower, boiled or steamed; brussel sprouts, boiled or steamed; spinach, boiled or steamed; carrots, boiled or steamed; seltzer, water; mayonnaise; salt; \*milk (limited), boiled; \*prunes (without the juice); \*pears, raw; \*bananas, raw; \*plums, raw; \*peaches, raw; \*cherries, raw; \*cantaloup, raw; \*honeydew melon, raw; \*cocoa (prepared).

Patients suffering from food allergy distinctly of the digestive system are rarely sensitive to the above foods. These foods also serve as hypo-sensitizers.

### CITATION OF ALIMENTALLERGY CASES

It was in 1922, when we began to follow the clue of alimentary food allergy. By 1925, we had fairly definite evidence of its existence, definite methods of treatment and the nature of results. Up to date we have treated nearly one thousand cases of alimentallergy, approximately half of them being ambulant, office patients. We cite several cases and call attention to certain special features.

*Case 1. Irritable Alimentallergy.* J. L. 27 years of age, female, married, one child, menses regular, weighing 86½ lbs. and measuring 5' 5", consulted us June 4, 1929.

*History and Complaints.* The patient had been vomiting for eight years, with remissions. She had been suffering also from nervousness, headache, nausea, heartburn, sour regurgitation, pressure in the epigastrium and a clogged feeling in her throat. During these eight years she gave birth to one child. The pregnancy of another had to be terminated on account of the extreme vomiting which became milder only, but did not cease after the termination of the pregnancy. She had consulted many physicians, went to many clinics and had been at one of the large hospitals in New York City for three weeks. There, many tests of her blood, spinal fluid, stomach contents and feces were made and gastrointestinal X-rays were taken, all of which proved to be negative. She vomited while at the hospital and continued to do so after being discharged from there and referred to the clinic. The patient came to us one year after she left the hospital.

*Examination.* The patient was a thin, pale individual with an anxious expression. Her heart and lungs were negative. The abdomen was scaphoid and tender in both iliac regions, otherwise negative. The nasal mucosa was red and the tonsils were large and spongy. The uterus was retroverted and the cervix lacerated. Rectal examination was negative.

*Diagnosis.* From the long duration of her complaints and from the negative findings at the hospital and at our office, we concluded that the patient was suffering from irritable alimentallergy.

*Treatment.* We instructed her to select her meals from the "anallergic foods" and especially to avoid the "allergic foods". We also gave her some medication but eliminated

\*Not allowed in the beginning or at any time should the symptoms recur, especially if bowels show tendency to move more than once daily.

it soon because she vomited immediately after taking it.

**Result.** All her symptoms including the vomiting disappeared in a few days. Her tonsils were removed on June 24, 1929. She continued to feel well on the diet and gained weight up to 104 pounds. After adhering a year to the "anallergic foods" she began to take small amounts of "allergic foods" occasionally. By the end of another six months she ate everything. Nevertheless, she was perfectly comfortable for another eight months.

**Recurrence.** On August 8, 1932, she began with nausea, heartburn, eructation and vomiting. She took cathartics and enemas for a week and became worse. On August 15, 1932, she presented herself at the office with these last named complaints. Examination proved her to be suffering from the same condition as at her first visit to the office, irritable alimentallergy. We advised her to return to the "anallergic foods", which advice, according to the subsequent statement of her husband, she did not follow. We did not hear from her for over a month when on September 29, 1932, we were called to her home. There, her husband informed us that she had insisted upon trying another physician who radiographed her alimentary tract, examined her blood and gastric contents and found them negative. He treated her for about a month without any improvement. By this time, the suffering from the gastrointestinal tract was so severe that she attempted to commit suicide by inhaling illuminating gas. After an ambulance physician revived her with the aid of a pulmotor, she asked her husband to call us.

During this visit her complaints were of the same nature but more pronounced. Examination revealed that she was suffering from irritable alimentallergy, as on several previous occasions. We advised her to resume the "anallergic foods", and were fortunate this time, because the nurse who was in attendance carried out our instructions faithfully. We also recommended an ice bag to the abdomen. The symptoms disappeared in a few days. She is well at this date.

**Comment.** It should be noticed, that the patient's complaints were confined to that part of the alimentary tract which extends from the mouth to the duodenum and were accompanied by general symptoms. She had no symptoms referable to the intestinal tract during the entire period of observation. Before she consulted us she had resorted to cathartics and enemas with the hope of relieving her gastric distress and her general symptoms. However, enemas or cathartics with frequent bowel evacuations had not cleared up her complaints. When the irritants were removed by excluding the "allergic foods," it mattered little whether she moved her bowels once a day or once a week, she remained comfortable in either event. The frequency of the bowel movements then depended upon the amount of food ingested. Little eating caused less frequent bowel movements, and the ingestion of much food caused more frequent or larger stools. This case is an example of *irritable gastrallergy*.

**Case II. Irritable Alimentallergy.** E. F., 26 years of age, female, married, two children, menses regular, weighing 135 pounds and measuring 5 feet 4 inches, consulted us February 18, 1928.

**History and Complaints.** The patient stated that she was suffering from constipation. On further interrogation it developed that she had one or two bowel movements daily. However, since she had a continuous desire to move her bowels she concluded that her bowel evacuations were incomplete. This condition she termed constipation. She used many cathartics without relief. She had consulted many physicians and they concurred in this opinion. They prescribed cathartics and enemas but the distress continued.

**Examination.** The physical examination including a rectal was negative. The urine was negative.

**Diagnosis.** Irritable alimentallergy. Since all symptoms were confined to the intestines the more specific diagnosis was *irritable enterallergy*.

**Treatment.** "Anallergic foods."

**Result.** Well up to date.

**Case III. Irritable Alimentallergy.** F. K., 28 years of age, single, school teacher, menses regular, weighing 95 pounds and measuring 5 feet, consulted us Jan. 7, 1925.

**History and Complaint.** Began many weeks ago, with several loose bowel movements daily, besides one solid evacuation. In addition to this she complained of gas in the stomach, distension of the abdomen and slight cramps at the time of moving the bowels. She also suffered from nervousness and occasional palpitation.

**Examination.** Patient appeared thin, pale and anxious. Blood pressure 120/80. Pulse 90. Urine negative. Basal metabolism: plus two. Stool contained blood but was negative to ova or parasites. Hemoglobin 65%. Nose and throat revealed an atrophic mucosa. Heart, lungs and extremities negative. The abdomen revealed fullness in the right side especially in the right iliac region, otherwise negative. Rectal examination negative. Gastrointestinal X-rays proved negative.

**Diagnosis.** Irritable alimentallergy.

**Treatment.** "Anallergic foods." Bismuth. Ice bag to the abdomen.

**Result.** The patient became well within a week.

**Progress.** The patient usually adhered to the "anallergic diet" during the attack and for a while after, but transgressed later. The result was that she had several attacks of diarrhea since then. In March, 1932, she had an attack of diarrhea accompanied by furuncles and arthritis. The diarrhea was controlled soon with the diet but the other symptoms continued. However, they cleared up after several hypodermic injections of a bacteriophage filtrate and a vaccine prepared from the patient's stool. Since then, the patient has adhered more strictly to the "anallergic foods" and remained free from gastrointestinal disturbances. This case is an example of *irritable colonallergy*.

**Case IV. Irritable Alimentallergy.** P. K., 34 years of age, male, married, weighing 185 pounds, and measuring 5 feet 8 inches, consulted us March 5, 1931.

**History and complaint.** The patient's most important complaint was that he could not move his bowels without a cathartic or an enema for many years. He also suffered from abdominal distension and borborygmi.

**Examination.** The physical examination was negative. Rectal examination revealed a large fecal mass.

**Diagnosis.** Irritable alimentallergy, more specifically irritable rectallergy.

**Treatment.** "Anallergic foods."

**Results.** The abdominal distension and the borborygmi cleared up in a few days. The only complaint the patient had for a while, was that when he attempted to move his bowels the fecal mass was too large to be evacuated conveniently. We instructed him to place the tips of his fingers on the perineum, a few inches to one side of the anus, and press to the opposite side and upward. This procedure thinned and cut the mass and facilitated its evacuation. This case is an example of *irritable rectallergy*.

**Case V. Autolytic Alimentallergy.** J. K., 44 years of age, male, married, weighing 133 pounds, and measuring 5 feet 3 inches, consulted us May 27, 1929.

**History and Complaints.** Eighteen years ago, the patient had typhoid fever. The only complication he could recall was blood in the urine (?) for two days. He recovered completely. Fourteen years ago, a pain began in the abdomen which continued for two years. His appendix was then removed and he felt well for four years. Eight years ago, the pain returned to the abdomen and in spite of all the treatment, the pain persisted up to the day he consulted us, with occasional remissions. He slept well and had one bowel movement daily.

*Examination.* General appearances was fair. Blood pressure 120 80. Pulse 60. Heart, lungs, abdomen, extremities, reflexes, nose and throat were negative. X-ray revealed a duodenal ulcer.

*Diagnosis.* Autolytic alimentallergy, more specifically autolytic duodenallergy.

*Treatment.* "Anallergic foods."

*Results.* The patient has been continuously well since he has been adhering to this diet. He gained fourteen pounds up to date. In June, 1930, gastrointestinal X-rays proved to be negative. This case is an example of *autolytic duodenallergy*.

The same striking results are seen in *infants* and *children*.

*Case VI.* H. W., a seven year old child whose father is a pediatricist, has been under our observation since June 20, 1932.

*History and Complaints.* The child vomited daily for years. The vomiting was preceded by pallor and faintness. Many physicians had treated him without success.

*Examination.* Examination proved negative.

*Diagnosis.* Irritable alimentallergy, more specifically *irritable gastrallergy*.

*Treatment.* "Anallergic foods."

*Result.* No vomiting up to date.

*Case VII.* S. F., a four and a half year old child whose father is a physician has been under our observation since July 10, 1932.

*History and Complaints.* The child vomited daily from birth and each vomiting was preceded by pallor and faintness. Many pediatricists had treated him without any beneficial effect.

*Examination.* The boy was thin and had a pale yellow complexion. Heart, lungs, abdomen, extremities, reflexes, nose and throat were negative.

*Diagnosis.* Irritable alimentallergy, more specifically *irritable gastrallergy*.

*Treatment.* "Anallergic foods."

*Result.* No vomiting up to date. The child gained weight, has good color and eats without difficulty.

#### GENERAL COMMENT

At the present there is considerable confusion in the literature of this subject; many authors bewail this fact, as is evidenced by the following:

Crohn (5) states that the terms indigestion, dyspepsia, gastritis, neurosis, hypersecretion, and achylia form indistinct concepts in our minds, the one overlapping and being confused with the other, and therefore not clearly comprehended. For the most part, it would take a jurist of note, or an experienced logician to decide, among a group of medical men, just what was meant by many terms used in gastrointestinal ailments. What one would term "hyperacidity," another might call a "hyperacid gastritis"; what is a "functional anacidity" to one, is a "gastric neurosis" to the other.

Matthes (6) remarks that every physician is familiar with the complaints of a "weak" stomach and intestines. There are individuals with very sensitive stomachs, who are subject to pyrosis which continues

irrespective of the quantity or the quality of food; they regurgitate sour fluid at times to such degree that it even irritates the gums; there is a demonstrable hypersecretion and hyperacidity of gastric contents and, with it, spastic constipation. At other times, constipation alternates with diarrhea. Such conditions are chronic. They often start in childhood, and it would seem that constitutional factors play an important role. The patients are not always neuropaths in the sense of neurasthenia, but they do have digestive organs more sensitive than do average people. The most characteristic feature is the constitutional element; perhaps it is more appropriate really to regard it as a constitutional anomaly.

Bassler (7) states that it is most probable that it will always remain impossible in the living subject to diagnose just what is the detailed picture of the stomach layers in a chronic gastritis. Gastric analysis, state of motility, length of history, and subjective symptoms are all we have to work upon, and, with these, in our present state of knowledge, and unless we accidentally gain particles of gastric mucosa for examination, much of the diagnosis in the ordinary run of cases remains as a supposition, and thus the most logical basis of treatment remains fixed upon rather symptomatic standards.

In discussing the treatment of "alimentallergy," all authors advise the patients "to take it easy, eat slowly, and eat the proper food," about which food each one has a different idea. In the beginning, it is usually advised to eat "delicate" foods, but a few days later when the patient complains of constipation, roughage again is added. All physicians advise laxatives, some with vigor, and some with caution.

We may read one chapter on gastroenterology after another, and one analytical author after another, and always we find the same confusion and the same despair.

#### CONCLUSION

The purposes of this paper have been:

(1) To demonstrate the possible etiology of about fifty gastrointestinal "diseases" described as separate entities without known causes, in all standard text books.

(2) To induce proof that all these fifty, separately described "diseases" really may be regarded only as different groups of symptoms of one disease viz "alimentallergy."

(3) To detail a method of preventing and neutralizing the distressing effects of this disorder of nutrition.

(4) To call attention to a method which obviates the customary routine of testing each patient for each *allergic food*.

(5) To submit a method of eliminating cathartics and enemas in the treatment of "alimentallergy," a condition from which it is believed that the great majority of those who need cathartics to produce bowel evacuations suffer.

## SECTION IV—*Roentgenology*

### Diverticular Sarcoma of the Stomach\*

By

JAMES T. CASE, M.D., D.M.R.E., F.A.C.S.  
CHICAGO, ILLINOIS

IT is very difficult to make a differential diagnosis between sarcoma and carcinoma of the stomach, as both the clinical and the roentgen findings are very much alike in the two forms of tumor. The age, the course, the results of palpation and the findings on examination of the stomach contents practically are the same in sarcoma as in carcinoma except that perhaps lack of free hydrochloric acid is rarer in the former than in the latter. Hemorrhage is seen in only about a third of the cases of sarcoma but when it occurs it is usually copious. Naegli (1) says that in some cases of sarcoma there is enlargement of the spleen and that, as this does not occur in carcinoma, it is a point in differential diagnosis. Metastases may occur at a greater distance and form larger masses than in carcinoma. There may be skin metastases which afford an opportunity for decisive microscopic examination of a biopsy specimen.

I have encountered two cases of sarcoma of the stomach in which I have had an opportunity to make a tissue diagnosis. One was a case of generalized gastro-intestinal lymphosarcoma in which the X-ray appearances were characteristic enough to form a basis for a correct diagnosis; the other case (presented here), was one in which a sarcoma developed in a diverticulum of the stomach wall.

A number of very elaborate papers have been published on sarcoma of the stomach, among which may be mentioned those in English by Haggard (2) and Douglas (3), (1920), by Balfour (4), (1930) and by D'Aunoy and Zoeller (1930). Haggard reviewed the subject up to 1920 and found that 244 cases had been reported in the literature, in 107 of which operation had been performed. Balfour recorded 54 cases from the Mayo Clinic. Masson (6) had previously reported 13 proved cases of gastric sarcoma from the Mayo Clinic including the cases up to 1920. Balfour found that between 1920 and 1930 the number had increased from 13 to 54. The diagnosis was made on operation in all but one, that one having been found on necropsy. In 5 cases no tissue was removed on operation, the surgeons having sufficient confidence in the gross appearance of sarcoma of the stomach to make the diagnosis from the macroscopic evidence. In three cases the pathologist was not quite sure, reporting "possibly sarcoma." D'Aunoy and Zoeller (5) report four personal cases and list the recorded cases in the literature

up to 1930, apparently without knowledge of Balfour's paper, bringing the number up to 335.

My limited experience with this rare lesion does not justify any dissertation on the general subject of sarcoma of the stomach, but the peculiar features of my second case in which the sarcoma was associated with a diverticulum warrant a detailed report of the case and some discussion. Myomatous tumors have often been observed to develop malignant properties after varying periods of benign growth. Schiller (7), Kimpston (8), Warner (9) and others report cases in which a tumor existed for a long period without causing symptoms but was finally removed because signs of malignancy developed; the microscopic diagnosis was sarcoma. Warner declares that a leiomyoma of the stomach may undergo sarcomatous degeneration just as may a leiomyoma of the uterus. Bachrach (10) believed that leiomyomata of the stomach may become malignant. Bullock (11), Haggard (2) and Fenwick (12) shared this opinion. Gosset, Bartrand and Loewy (13), however, maintain that many of the pediculated so-called "sarcomata" of the stomach are and remain benign.

There has been a further discussion as to whether in leiomyosarcomata of the stomach the smooth muscle cells have become transformed directly into sarcoma cells or whether the myoma has been invaded secondarily by a sarcoma originating from the connective tissue of the stroma. In the cases of Brodowski (14) and Virchow (15) direct sarcomatous degeneration of a leiomyoma of the stomach wall is described, and in the case of Gouilloud and Mollard (16) the pathologist who made the histological examination concluded that it was a tumor developed from smooth muscle tissue. Lecène and Petit (17), however, consider it much more probable that the connective tissue stroma of a myoma has undergone sarcomatous degeneration.

As both sarcoma and diverticulum of the stomach are unusual it is extremely rare to find the association of the two lesions in the same patient. Benign growths have been reported in diverticula of the stomach. Sandström (18) in 1929 reported a case of this rare lesion, interesting from the point of view of differential diagnosis, in which roentgen examination of the stomach showed narrowing of the lumen of the pylorus which had the appearance of a defect, in the center of which there was a niche-like opaque spot. A tentative diagnosis of ulceration surrounded by infiltration was made from the roentgen findings. On operation the surgeon found a benign tumor-like hyperplasia of the

Fig. 5. Low power (23 x) photomicrograph of section of diverticular sarcoma of stomach.

was congenital and that the degeneration took place later in life. He refers to three cases of myoma described by Puskeppelies (20) in which that author expressed the opinion that the myomata were primary and the diverticula had formed in the tumor tissue. Cleve rejects this interpretation and thinks the diverticula were primary. He believes his tumor was sarcoma though there were no metastases and no infiltrating growth. The predominant cells of the tumor showed a decided similarity to smooth muscle cells, particularly in the form of the nucleus; they also resembled the cells of spindle-cell sarcoma. He assumes that the tumor cells had originated from connective tissue cells and in the process of further differentiation had stopped at the stage of smooth muscle cells.

Müller (21) describes a carcinoma diverticulum of the stomach.

In the light of these reported cases of diverticular tumor and the interesting fact that, in my own case which will now be reported, there was a tumor in the wall of a diverticulum diagnosed on microscopic examination as sarcoma, the question arises whether there was not primarily a leiomyoma of the stomach which later became malignant.

#### CASE REPORT

Mr. C. L. E., age 52, reported for examination and treatment on February 24, 1930. He complained of biliousness and dizziness and headaches with anorexia dating back about a year. I found that he had had the usual diseases of childhood, including typhoid when about 14. Thirteen years ago he went to New Mexico on account of pulmonary tuberculosis; the present examination showed healed tuberculous lesions of the lungs. In New Mexico he increased from 115 to 143 pounds in weight, which he maintained until recently when he began to suffer digestive disturbances. His weight had fallen to 110 pounds,

pyloric glands in the submucosa and muscularis, surrounding a central diverticulum, from which he made a diagnosis of diverticular adenoma, or more correctly perhaps, an adenomatosis combined with a diverticulum.

Such benign diverticular tumors (diverticular myomata or adenomata) are very rare and Sandström was able to find only one case reported in the earlier literature in which roentgen examination had been made. In that case also the roentgen findings were wrongly interpreted. Because of the joint presence of a diverticulum and a tumor in these cases diagnosis based on the roentgen ray findings alone is extremely difficult. A niche-like opaque spot surrounded by a defect in the gastric shadow has been recognized as a characteristic feature of malignant ulcer, though it has been found in some of the larger calloused ulcers also. It is almost impossible, therefore, to exclude ulcer in cases in which ulcer or cancer is suspected on clinical grounds. To make a correct roentgen diagnosis these cases might be followed up with repeated examinations for some considerable time, preferably after an ulcer regime, after which the findings should remain stationary if it is a case of tumor; but valuable time would be lost in the waiting. In these cases absence of spasm is a point against ulcer. The absence of blood in the stools is also an important point in the differential diagnosis from ulcer.

One of Balfour's cases was a sarcoma in a diverticulum and Cleve (19) reports a case. Though his title is "diverticular myoma of the stomach," he concludes from the histological examination that the tumor was a sarcoma. The patient was a man of 61. Necropsy showed a diverticulum of the stomach which had been transformed entirely into a tumor that had undergone sarcomatous degeneration. He thinks the diverticulum

Fig. 6

Fig. 6. High power (550 x) photomicrograph from resected tumor.

but under the care of Dr. Mendelson he had regained 14 pounds.

Our examinations showed old scars of tuberculosis in the apices of the lungs and marked enlargement of the spleen with calcifications. The roentgenogram of the stomach showed a crater at about the middle of the body of the stomach, about one-half inch in diameter, surrounded by a filling defect which we believed represented a tumor. The remainder of the gastro-intestinal examination was without importance. The blood count showed 4,750,000 red cells and 11,500 whites. The urine findings were normal. Gastric analysis showed free hydrochloric acid as high as 45 at the end of an hour, and gross blood in the fasting stomach contents. The pre-operative diagnosis was an "ulcerating lesion in the middle of the body of the stomach, rather near the greater curvature, with tumor formation."

On operation, I found such a large tumefaction around the apparent ulcer that I felt that the lesion must be malignant. There was a mass measuring 4.5 cm. in diameter along the base located on the anterior wall of the stomach near the greater curvature and extending 2.5 cm. from the outer surface of the stomach. The tumor was resected together with the distal portion of the stomach by the method of Polya, making the gastrojejunal anastomosis retrocolic. The liver was normal.

The specimen showed a diverticular formation, the crater being an inch deep and apparently having an ulcer at its

base. It is interesting to note that there were no adhesions to the diverticular mass except a few omental tags, so that a traction diverticulum hardly could be considered.

On gross examination the mucosa was found to be smooth and free from change except for a sharply punched-out opening which communicated with the hollowed out interior of the mass seen externally. This interior surface was ulcerated, rough and irregular, covered by fibrin. The wall was firm, pinkish-white in color, with numerous hemorrhagic areas.

Microscopic study by Dr. H. R. Fishback follows:

Sections cut from the localized out-pouching of the stomach wall show microscopically ulceration with entire loss of mucosa, the ulcer base being covered with fibrin, beneath which is granulation tissue mingled with tumor cells. Tumor cells comprise a mass making up almost the entire thickness of the wall with infiltration and destruction of the mucosa, submucosa and muscularis. The cells are arranged closely together with a small amount of fine reticulum. They are of various sizes and shapes, mostly of rounded or cuboidal form. The nuclei are large, tend to hyperchromatism and are of loose reticulated structure. Mitotic figures are not seen. Many blood spaces are found lined by tumor cells.

Diagnosis: Mixed cell sarcoma of the stomach.

The patient at last report, nearly three years after operation, weighed about 135 pounds and was able to carry on his usual occupation of store manager.

## ABSTRACTS

PFÄHLER, G. E.

*The Roentgenological Diagnosis of Meckel's Diverticulum.* *S., G. and O.*, Vol. LIX, No. 6, Dec., 1934, pp. 929-935.

Meckel's diverticulum has been defined as a diverticulum of the small intestine varying in its length, the diameter of its lumen, and in its position on the terminal part of the ileum. It exists in about two per cent of all individuals, and is commonly found at autopsy.

When inflamed it gives rise to symptoms which resemble those of acute appendicitis. Fibrosis at its base may cause intestinal obstruction. Intussusception may occur at the site of the diverticulum. Perforation of a peptic ulcer of Meckel's diverticulum produces signs of acute intestinal perforation. The most frequent symptom, however, is

haemorrhage from the bowel. When this occurs in a child, one should think first of a Meckel's diverticulum.

In the author's experience repeated examinations of the small intestine may be necessary to show the diverticulum. In making such examinations one should keep in mind that the diverticulum may be located at any point on the circumference of the bowel. The diverticulum may be filled with a non opaque substance preventing the entrance of barium. The characteristics of the diverticulum are the same as those of any diverticulum; it is apt to show peristalsis. The author reports 2 cases in which the diagnosis of Meckel's diverticulum was made roentgenologically, and found at operation.

Six figures accompany the article.

## SECTION V—*Therapeutics*

### The Use of Duodenal Extract as an Adjuvant in the Treatment of Benign Peptic Lesions: Report of Eight Cases\*

By

ANDREW B. RIVERS, M.D.  
ROCHESTER, MINNESOTA

IN October, 1934 (11), I suggested that some beneficial results might accrue from the use of an extract of duodenal mucosa and submucosa as a supplement to approved methods of treating benign peptic lesions. Thus far more than fifty patients have been treated in this way, many of them with encouraging results. In this paper are reviewed the results in a few of the cases in which this treatment was used. That this method of treatment in no way reduced the effectiveness of other methods of therapy, indeed that the usefulness of other methods may have been augmented by such a procedure, is suggested by the clinical as well as by the roentgenologic results obtained in these cases. It should be stated here that no form of treatment which considers solely the early symptomatic results, even though these be most encouraging, can merit serious consideration unless such results give some promise of enduring benefit.

It is well known that many types of treatment instituted for the relief of the symptoms of peptic ulcer may be very effective in controlling the distress associated with this disease. The medical literature and physicians' correspondence are deluged by well-sponsored new treatments for ulcer, which are welcomed and tried with enthusiasm only to be discarded and forgotten with equal promptness. These treatments last just long enough for the normal cycle of re-appearing difficulties to return, and on the re-institution of symptoms each system in turn loses cast, and there is a return to the old approved methods of treatment.

The cases reported in this paper have not been observed sufficiently long to permit drawing any definite conclusions regarding the usefulness of duodenal extract in the treatment of ulcer. I am encouraged in continuing to use it, however, because not only were these patients relieved of their symptoms, but in all cases included in this particular report there was roentgenologic evidence of ulcers having healed.

#### A CONSIDERATION OF SOME OF THE CAUSES OF ULCER AND A RATIONALE FOR THE USE OF DUODENAL EXTRACT

Treatment of any disease should include some plan whereby factors of known etiologic importance can be recognized and some effort made to subjugate or ameliorate them. Although there are many interrelated factors which are important in the causation of ulcer, these ultimately resolve themselves around two, the

one inherent in the ulcerating potentiality of acid-pepsin, the other maintained in the defense which the tissues possess and by which they protect themselves against the eroding action of the gastric chyme. It would seem that the alternating activity and quiescence which are so characteristic of such lesions would be evidence of two forces, the one of aggression and the other of defense, and that the outcome would depend on which factor was dominant at any particular stage of the life cycle of peptic ulcer.

Physiologists have amply demonstrated the increased vulnerability of tissues to the eroding action of gastric juice which has greatly accentuated acid-pepsin values. The factors of aggression inherent in acid-pepsin, however, are ordinarily insufficient to produce ulceration in tissues which maintain their normal mechanisms of defense.

*Defense mechanisms of duodenal mucosa.*—Mann and Kawamura made some inquiries into the protecting, defensive mechanism of duodenal mucosa. They completely removed the duodenum of experimental animals; a loop of jejunum was then placed where previously the duodenum had been, thus reestablishing the regular continuity of the gastro-intestinal tract. The bile and pancreatic juice were drained into the jejunum, thus retaining the normal, physiologic extraduodenal antacids. In 20 per cent of cases ulcers developed at the point where the jejunum was anastomosed to the stomach. This suggests that the duodenal mucous membrane includes a protecting mechanism that is not possessed by the jejunal mucosa. It is not fully understood whether this increased resistance is inherent in the duodenal cells, whether the cells produce a secretion that adheres to the mucosa and makes it less vulnerable, or whether a substance is elaborated in the wall of the duodenum that alters gastric chemism to curtail its eroding properties.

Baker, Florey and Harding were of the opinion that the normal secretion of Brunner's glands aids in protecting the mucosa from injury by the acid chyme. Florey and Harding intimated that the specific factor of protection may lie in the mucoid consistence and contained alkalies of the product of these glands. Kosaka, Lim, Ling and Lui, and lately, Ivy have suggested that intestinal mucosa contains a substance which is absorbed and causes inhibition of gastric secretions.

*Defense factors inherent in pancreatic juice and bile.*—Mann and Williamson further pointed out the

Submitted March 16, 1935.  
\*Division of Medicine, The Mayo Clinic.

protective importance of the secretions which are poured into the duodenum by glands that are extrinsic to the gastro-intestinal tract. They performed some experiments in which the bile and pancreatic juices were drained away from the duodenum into the ileum. In 50 per cent of such cases peptic ulcer developed. In these experiments normal gastroduodenal continuity was maintained, the gastric chyme impinging on the area intended by Nature to receive it; yet, the loss of pancreatic juice and bile was sufficient to disturb the balance between the aggression mechanism inherent in the chyme and the defense mechanism inherent in the duodenal tissue, at any rate sufficiently so that dissolution of the duodenal mucosa occurred in 50 per cent of such cases.

McRoberts showed that the *pH* of the duodenum is maintained toward the acid side for much longer periods following a fat meal when the bile has been diverted in such a manner that it does not reach the duodenum. Hoerner evulsed the pancreatic ducts, making it impossible for the pancreatic secretion to enter the duodenum; he found that under such conditions the acidity of the duodenum was greater and was maintained for much longer periods. It would appear, therefore, that the bile and pancreatic juice have an important rôle in protecting the duodenal mucosa against the eroding action of the acid chyme. Duodenal mucosa elaborates *secretin* and possibly other hormones which act upon the pancreatic and possibly the biliary output.

*Defense factors inherent in duodenal chemism and mucosa.*—Mann and Williamson also developed experimental procedures by which the gastric contents were led directly into the jejunum without receiving the admixture of bile, pancreatic, and duodenal secretions. They drained the duodenal content into the ileum. Furthermore, the possible protecting mechanism of the duodenal mucosa was eliminated by substituting the jejunum where normally the duodenum existed; thus the possibility of protection from duodenal mucosa, duodenal secretions, and from bile and pancreatic juice was not available and the jejunal membranes had to resist, as well as possible, the eroding action of the acid chyme. Following this procedure, jejunal ulcers developed in 95 per cent of cases.

*Breakdown of duodenal defenses against acid-pepsin erosion.*—Stevens, in studying the capacity of the duodenum to neutralize and buffer acid, demonstrated that this organ had a remarkable reserve function in this respect, which was materially in excess of its ordinary physiologic requirements. That it will break down, however, under the necessity of neutralizing without interruption the acid chyme is shown by the work of many physiologists. Mann and Bollman instilled 0.4 per cent hydrochloric acid into the stomachs of dogs at a rate of less than 1 c. c. each minute for about eight hours daily. These animals appeared to get along very well for several weeks, after which time peptic ulcers usually developed.

Baker, Florey, and Harding studied the effect of hydrochloric acid on the duodenal cells of animals which had been fed it. Baker sacrificed his animals at varying times after feeding them hydrochloric acid of 0.2 to 0.5 per cent concentration. The first response of the duodenal cells to the feeding of acid was to pour out copious amounts of secretion. This was also noted by Florey and Harding. Baker additionally found that, if he continued to feed acid, the duodenal epithel-

ium would promptly disintegrate. If this was continued, bleeding from the membrane usually would result. On the other hand, if the feeding of acid was stopped, a remarkably rapid regeneration was noticeable, and in forty-eight hours the epithelium was usually again normally intact.

Gastric secretory rates are usually accentuated among patients who have peptic ulcer. This is especially noticeable among patients with duodenal or jejunal ulcer, and particularly so during periods when there is definite ulcer activity.

For some time I have been interested not only in the height of the acid concentration and peptic activity, but also in the ability of the chief and parietal cells to maintain a vigorous secretory rate for unusually long periods. It has often been noted that, following the use of histamine, patients with peptic ulcer continued to secrete a highly concentrated acid for considerable periods after a drop in acidity would ordinarily have been expected. If such cellular behavior actually obtains in response to other stimuli, it would be obvious that the gastroduodenal defense mechanisms of patients with peptic ulcer might be forced to exert themselves accordingly. It would seem to me that this adequacy in defense is one of the crucial factors in the cause of ulcer and that it would therefore merit special consideration in the treatment of such lesions. It seems logical that the activity of the defense mechanisms would have to fluctuate in proportion to changes in the potency of the mechanisms of aggression: with prolonged and sustained elevation of acid-pepsin secretion would develop a correspondingly vigorous effort of the cells to throw out defenses against such accentuated tendencies to erosion. Ordinarily, the daily physiologic fluctuation in the curves of acidity shows alternate periods of rapidity and retardation of the secretory rate, thus giving the cells "breathing spells" during which the forces of defense could be adequately reestablished. Physiologists have shown that *continuous* feeding of hydrochloric acid is likely to cause the eventual break-down of the cells called upon to resist the digestive action of the gastric chyme. It seems reasonable to assume that an important cause of such cell dissolution, which results in peptic ulcer, lies in the exhaustion of the defensive powers of the cells: they may have used up their own as well as all available reserve sources of defense.

The curve above the line in the upper portion of Figure 1 indicates the height of hydrochloric acid concentration following the use of histamine in Case 1 in this paper; the curve below the line is an exact inversion, or a mirror reflection, of the same curve. It will be noted that the acids remain relatively high for a prolonged period. The curve above the line in the lower portion of Figure 1 indicates a hydrochloric acid concentration following the administration of histamine to a patient who did not have peptic ulcer; again, the curve below the line is an inversion of the upper curve. The return to basic levels is relatively rapid. This serves to illustrate the wide differences which might exist in the requirements for tissue defense. The mirrored or inverted curves are drawn to illustrate the hypothetical degree of "protective" activity required of cell defense mechanisms, assuming that the comparative degree of activity of cell defense parallels to some degree the height and persistence of chief and parietal cell activity.

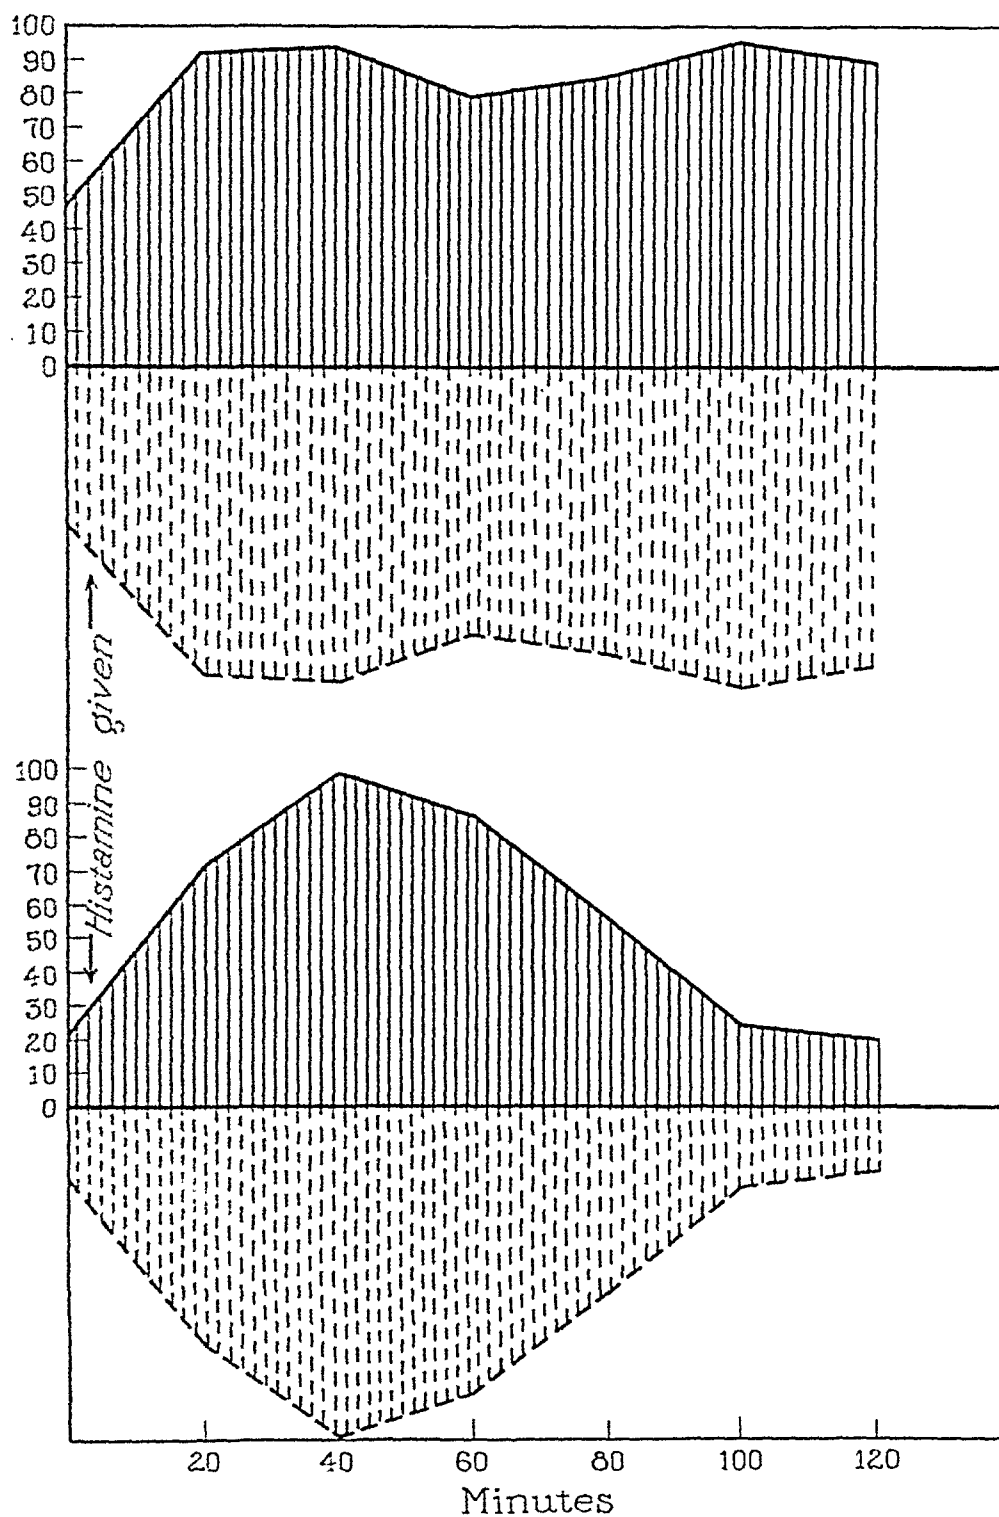

Fig. 1. Curves of free HCl concentration: UPPER, after administration of histamine to ulcer patient, Case 1; LOWER, after administration of histamine of a patient who did not have peptic ulcer.

In most instances present methods of treatment concern themselves mainly with the reduction or neutralization of gastric acidity. Admittedly, healing seems to be favored when this is accomplished; however, so soon as the acidity of the gastric chyme gets out of control, the threat of further erosion appears. Treatment of peptic ulcer would be more effective if somehow instead of diluting the acids and curtailing the peptic activity, the secretory rate of the chief and parietal cells could be subjugated or controlled at will. It seems that the defense mechanisms also need occupy the attention of those who are concerned with the problems of ulcer therapy. If total duodenal or gastric defense functions could be augmented, if specific substances could be made available so that we could control the duodenal secretions as well as the juices entering the duodenum, the problems of ulcer therapy would no doubt be greatly simplified.

In formulating a plan to support or reestablish tissue defenses, it would be well to take into consideration certain pertinent observations made by physiologists. The duodenal cells seem especially resistant to erosion by acid-pepsin. One of the first responses that occurs in animals when it might seem necessary for these cells to protect themselves is the throwing out of a copious amount of an alkaline secretion. This seems mainly to be a product of the glands of Brunner. Florey and Harding suggest that "malfunctioning of these glands may be primarily responsible for duodenal ulcer." At any rate, this secretion probably plays some rôle in protecting duodenal mucosa. It would seem, therefore, that if this secretion could be maintained or increased, or if the product of these glands could in some way be supplied to the duodenum, its protective powers might be restored or more consistently preserved.

The absence of bile and pancreatic juice definitely increases the vulnerability of the duodenal cells to erosion by acid chyme. Whether this is so because of the chemical reactions within the duodenum, or whether the availability of bile and pancreatic juice for gastric regurgitation constitutes the intimate mechanism of protection, seems of no great importance. The assurance that liberal amounts of bile and pancreatic juice are present in the duodenum might therefore be desirable in the treatment of ulcer. Secretin is elaborated in the duodenal mucosa, and perhaps other hormones as well and this affects the output of pancreatic juice and possibly bile. Some attention to ways of safeguarding the availability of these substances would also be useful in the treatment of ulcer. Furthermore, the evidence that the intestinal wall prepares a substance which is an inhibitor of gastric secretion is interesting and important. Treatment of peptic ulcer might be greatly improved by the use of such a substance. If by any means the work of the duodenal cells can be facilitated, if protective, alkaline duodenal secretions can be abundantly maintained, or if a product of the intestinal wall which lowers gastric acidity becomes available, progress in the treatment of peptic ulcer will be assured.

Prompted by the desire to make available certain substances which might be useful in the defense or rebuilding of besieged gastroduodenal tissues, an extract of duodenal mucosa and submucosa was prepared and supplied to patients who were suffering with peptic lesions. This extract was not intended to be used as a substitute for other therapeutic measures

but as a supplement to other methods of treatment.

In a previous paper I (10) pointed out that there must be several interacting factors responsible for the genesis and chronicity of peptic lesions. The most important of these factors were: (1) local traumatization of tissues, as by infected emboli, (2) acid-pepsin aggression and resistance of tissues to erosion, and (3) certain systemic factors, of which neurogenic influences seemed the most important. Since peptic ulcer is probably the result of interaction of several or all of these factors, it becomes necessary in formulating a plan of treatment to direct attention to all of them.

#### METHOD OF USING DUODENAL EXTRACT IN TREATMENT

The extract which has been used at this Clinic is obtained from the mucosa and submucosa of the duodenum of hogs.\* We are also using an extract made from the mucosa and submucosa of the pyloric portion of hogs' stomachs. At the present time Dr. Foley, Dr. Goldsmith and I are preparing a more detailed analysis of the early results noted from the use of these extracts in more than sixty cases. In all of the cases reported in this paper, the patients have been hospitalized and have been kept under careful observation. They were kept in bed for two or three days, following which they were permitted to be up three or four hours daily. During the first few days they were given a diet consisting almost exclusively of milk. Four ounces of milk were given every hour, beginning at 7 a. m. and continuing to about 9 p. m. In a few instances hourly feedings of milk were supplemented by the use of cereal, custard, and cream soup at meal times.

About the third day of treatment the intake of food was increased and patients were given small meals, consisting of soups, cereals, custards, puréed vegetables, and food of like consistency. Frequent feedings of milk throughout the day were continued. At 9:30 a. m., and at 2:30, 5:30 and 9:30 p. m., they were given 15 grains of alkali. At 10:30 a. m. and at 3:30 and 7:30 p. m., 30 grains of extract were given; this was usually mixed with 2 ounces of malted milk, egg-nogg, or grape juice. Sedatives and belladonna were used three or four times daily. Usually, after five or six days, the patients were given a bland type of diet, similar to that given to ambulant patients with ulcer. Milk was given once between meals and at 9 p. m. Twenty grains of alkali were then given an hour after meals, and 30 grains of duodenal extract were given at 11 a. m. and at 4:30 and 7:30 p. m. Throughout the period of hospitalization these patients were given mineral oil or olive oil several times daily.

The patients were then dismissed with the recommendation that they continue to take a bland, non-irritating diet and that they use 20 grains of alkali at 9 a. m., 4 p. m. and 7:30 p. m. Additionally, it was suggested that they take 30 grains of the extract, with a glass of milk, at 10:30 a. m., 3 p. m. and before retiring.

#### REPORT OF CASES

*Case 1.—Duodenitis type of duodenal ulcer.*—A man, aged twenty-four years, came to this Clinic complaining that for three years he had experienced reappearing episodes of epigastric distress. His symptoms reached their maximal intensity two hours after meals, and he was

\*Dr. Klein, of the Wilton Laboratories in Chicago, has kindly furnished us with this Extract.

usually relieved by the ingestion of food or soda. During the previous year there had been some intensification of his symptoms and he had noted less adequate relief by the use of soda. Physical examination was negative. Roentgenologic investigation revealed the presence of a "duodenitis type of duodenal ulcer". He was hospitalized in August, 1934, and placed on a Sippy regimen. Under histamine stimulation the gastric acidity rose to 124 for total acids and to 106 for free hydrochloric acid. The amount of pepsin was tremendously increased, rising on one occasion to 9000 units. The patient's diet was gradually increased and the regimen was supplemented by the use of 50 gm. of mucin daily. He was dismissed on an ambulatory regimen which consisted of a bland diet and 60 grains of alkali and 60 gm. of mucin daily. He was advised to curtail his activities and to obtain more rest. He improved temporarily, but after several months was again having trouble.

He returned and was again hospitalized. This time he was given a bland diet and 60 grains of alkali and 90 grains of duodenal extract daily; in addition he was given atropine and a barbiturate four times a day. He improved promptly and, after eight days, roentgenologic evidence of duodenal deformity had disappeared completely.

*Case 2.—Jejunitis following gastro-enterostomy.*—A man, aged fifty years, had at the age of forty-five undergone a posterior gastro-enterostomy and appendectomy for duodenal ulcer and appendicitis. He had been well for eighteen months following this operation, but during a period of much worry and tension he again had indigestion, which suggested recurring peptic ulcer. A roentgenogram was taken and gave evidence of a jejunal deformity that was assumed to be a jejunal ulcer. He was placed on a medical regimen and he improved promptly. Several months prior to his admission to this Clinic, he had again had indigestion and this had been complicated by the vomiting of blood. He had also noted tarry stools for a week. A month before admission he had had another hemorrhage.

On examination, there was evidence of secondary anemia. Roentgenologic examination showed a deformed duodenal cap; additionally, there was a definitely deformed region in the jejunum, which was assumed to be due to an "area of jejunitis". The patient was hospitalized and placed on a third-week Sippy diet. He was given 60 grains of alkali and 90 grains of duodenal extract daily. He was also given barbiturates and atropine twice daily. He promptly improved and, after eight days' hospitalization, another roentgenogram was taken. At that time the deformity of the jejunum had disappeared completely.

*Case 3.—Duodenal ulcer with a large crater.*—A man aged sixty, stated that for the past three years he had had indigestion, which frequently had been intensified during the spring and autumn. These episodes had lasted for a variable length of time, usually for two or three weeks. The pain was midepigastria in situation and occasionally was projected toward the right costal margin. The distress reached its maximal intensity from one to two hours after the ingestion of food and was relieved by soda or milk. The patient had noted tarry stools on one occasion. There was some evidence of dental infection but physical examination otherwise revealed nothing of importance. A roentgenogram of the gastro-intestinal tract disclosed a duodenal ulcer with a large crater. Estimation of the gastric acidity gave values of 100 for total acids and 90 for free hydrochloric acid. The amount expressed was not unusual. The infected teeth were removed, and the patient was hospitalized December 8, 1934. He was put on a bland diet, and was given 60 grains of alkali and 90 grains of duodenal extract daily. He was also given barbiturates and belladonna twice a day. His

symptoms promptly disappeared. On December 21, 1934, he was reexamined under the fluoroscope and at that time the crater in the duodenum had disappeared completely.

*Case 4.—Duodenal ulcer with a central crater.*—This patient, a man aged thirty-four, presented himself for investigation because of indigestion which had begun seven years ago. Four years prior to admission a diagnosis of peptic ulcer had been made, whereupon he had been placed on a Sippy regimen with prompt relief of symptoms. He had remained well for about a year, but had then manifested recurring difficulties by vomiting a copious amount of blood. Subsequently, he had had intervals of epigastric distress, varying in severity. During the last few months he had trouble with his stomach every day. This had been characterized by pain in the midepigastrium, which had come on from one to one and a half hours after meals and had been relieved by the ingestion of food or soda. Nothing unusual was demonstrated on physical examination. Estimation of gastric acidity, following the use of histamine, showed a maximum of 126 for total acids and of 110 for free hydrochloric acid. Roentgenologic investigation revealed the presence of a duodenal ulcer with a central crater. The patient was placed on a bland diet, and was given 60 grains of alkali and 60 grains of duodenal extract daily. Additionally, he was given a barbiturate and atropine three times daily.

After two weeks' hospitalization, a second roentgenologic examination of the gastro-intestinal tract was made; at that time, no duodenal ulcer crater could be visualized either under the fluoroscope or in the roentgenogram.

*Case 5.—Gastric and duodenal ulcers.*—A woman, aged thirty-six on admission to this Clinic, at the age of eighteen had had her appendix removed. Five years later she had undergone an operation for intestinal obstruction and two years after that, at the age of twenty-five her gall-bladder had been removed. All of these operations had been performed elsewhere. Following the cholecystectomy the patient had been well for two years. She had then, however, begun to have epigastric distress, which came on thirty minutes after meals and was relieved by the ingestion of soda. Three years before her admission to this Clinic she had been placed on an ambulatory ulcer regimen, with some relief of symptoms.

At the time of consultation at this Clinic the patient was having distress in the right hypochondrium, slightly to the right and slightly above the umbilicus; in addition, she experienced pain near the left costal margin. This was at times projected through to the lower left scapular region. These pains reached their maximum twenty to thirty minutes after meals and were relieved by taking food or soda. Except for some dental infection, physical examination revealed nothing of significance. Roentgenologic investigation disclosed the presence of an ulcer on the posterior wall of the stomach near the lesser curvature and just above the angle, as well as of a duodenal ulcer.

The patient elected to try a medical regimen for the treatment of these ulcers. She was hospitalized and given a bland type of diet, with frequent feedings of milk between meals. She was also given 60 grains of alkali and 90 grains of duodenal extract daily. Barbiturates and belladonna were used three times a day. Frequent aspiration of the gastric contents during the course of hospitalization revealed free acids ranging from 28 to 40; under stimulation with histamine total acidity reached 80 and free hydrochloric acid 68. There was definite clinical improvement; the stools after the first few days in the hospital were negative for blood, and sixteen days after treatment was begun roentgenologic investigation showed that the gastric ulcer had disappeared completely.

*Case 6.—Gastric ulcer.*—This patient, a man fifty-seven years old, stated that for three years he had had intervals of epigastric distress which had been especially troublesome in the spring and autumn. His pain was situated to the left of the midline near the costal margin, and it

reached its maximal intensity one and a half to two hours after meals. He was occasionally awakened at night, between midnight and 2 a. m. Milk and alkalis had invariably relieved the distress. In the six months preceding admission to this Clinic the distress had been more severe and had been less amenable to the usual methods of obtaining relief. Determination of gastric acidity gave values of 70 for total acids and 58 for free hydrochloric acid. A roentgenogram disclosed a perforating ulcer on the posterior wall of the stomach near the lesser curvature and just above the angle.

The patient elected to try a medical regimen and was hospitalized. He was placed on a bland diet and given 60 grains of alkali and 90 grains of duodenal extract daily. In addition, he was given barbiturates and atropine twice daily, and 1 ounce of olive oil at 9 p. m. His improvement was very prompt and, after eight days' hospitalization, another roentgenogram of the stomach was taken. At that time the ulcer on the lesser curvature of the stomach had almost completely disappeared. Because of financial reasons, however, it was impossible for the patient to remain any longer for treatment.

Examinations of the stool were persistently negative for blood. The patient was advised to continue on this regimen and to report for reexamination after three weeks.

*Case 7.—Recurring duodenal ulcer following a Billroth I operation.*—A man, thirty-four years old, had begun having indigestion five years prior to his admission to this Clinic. The distress was in the midepigastrium and reached its maximal intensity from one and a half to two hours after eating. The use of soda usually would promptly relieve the symptoms. At intervals the patient had been nauseated and occasionally he had vomited. He was examined at this Clinic and found to have multiple duodenal ulcers.

Estimation of gastric contents gave values of 88 for total acidity and 78 for free hydrochloric acid; 160 c. c. were aspirated. At operation this patient was found to have multiple duodenal ulcers with diffuse duodenitis. Partial duodenectomy, partial gastrectomy, a Billroth I type of operation was performed. His convalescence was without incident. He remained well for about five months, when recurring indigestion developed, with symptoms similar to those for which he was operated on.

The patient returned for examination and on roentgenologic investigation was found to have recurring ulcer at the site of the anastomosis. Estimation of the gastric contents following the use of histamine showed a maximum of 61 for total acids and 58 for free hydrochloric acid. A correct reading was not obtainable because all of the specimens recovered contained bile. The patient was hospitalized and placed on a bland diet, the amount of which was gradually increased, he was given 90 grains of alkali and 90 grains of duodenal extract daily. Additionally, he was given barbiturates and atropine four times daily. One infected tooth was removed. He gradually improved. A roentgenogram taken four weeks after the onset of treatment showed complete disappearance of the ulcer niche.

*Case 8.—Recurring duodenal ulcer following a Billroth I type operation.*—This patient, a man aged forty, stated that he had begun to have indigestion at the age of twelve. Even at that early age there had been some suggestion that he had a peptic ulcer. At the age of seventeen, a diagnosis of peptic ulcer had been made, and he had been put on Sippy treatment with temporary cessation of symptoms. At intervals following this he had experienced indigestion, and by the time he had reached twenty-nine he was having severe and debilitating digestive disturbances. The distress which, previously, had come several hours after meals and had been relieved by food and soda, now had become constant and less amenable to the accustomed methods of obtaining relief. Finally, the ulcer had perforated, and it had been necessary to perform an emergency operation, at which time a purse-string suture had

been applied to the ulcerated region. Two years later the ulcer had given him so much trouble that it was necessary to operate again. A posterior gastro-enterostomy had then been performed. Following this the patient had been perfectly well for two years, whereupon recurring indigestion had appeared which had many of the characteristics noted previously. In addition to the epigastric distress, he experienced pain to the left of the umbilicus, and this pain was projected downward to the testis. The distress came on several hours after meals and was relieved by soda.

On three occasions the ulcer had bled profusely. In August, 1934, the patient was reexamined at this Clinic, and he was found to have an ulcer on the anterior wall of the gastro-enteric stoma. Partial gastrectomy, partial duodenectomy, a Billroth I type of anastomosis, was performed. His convalescence was without incident. Very soon following this operation, however, he was again having trouble with his stomach. Again the syndrome was that usually experienced by patients with peptic ulcer. He returned for examination five months after the operation. Roentgenologic examination revealed the presence of a recurring ulcer at the gastroduodenal anastomosis. He was hospitalized, put on a bland diet, and given 60 grains of alkali and 90 grains of duodenal extract daily. In addition, barbiturates and atropine were given three times a day. He improved promptly. After fourteen days had passed he was reexamined fluoroscopically and the niche previously demonstrated at the site of anastomosis had disappeared completely.

#### COMMENT

It will be noted from a review of these histories that the treatment instituted for these patients represents a combination of various methods already generally found useful in the therapeutics of ulcer.

The general plan of diet is that so effectively used by Sippy and his colleagues. Instead of very gradually increasing the amount of food taken, however, this was increased rapidly, so that after four or five days the patients were taking a rather liberal diet, such as that usually given patients on ambulatory regimens.

The usefulness of alkalies in the control of the symptoms of peptic lesions is one of the established principles of ulcer therapy. The reduction of acidity will probably always remain one of the principles about which the treatment of ulcer must be built. Large amounts of alkali were not used. I believe that moderate amounts of soda, calcium, or magnesium have a well merited place in the therapeutics of ulcer. The use of sedatives and belladonna has been continued in the belief that the treatment of ulcer is facilitated. Whenever possible the scrupulous removal of foci of infection is advised.

It is not expected that the extract of duodenal mucosa and submucosa will prove to be a specific for peptic ulcer, for I do not believe that any single substance will ever be able to correct all the interacting factors responsible for the genesis and chronicity of this disease. I am fully convinced, however, that if some of the protecting mechanisms inherent in duodenal mucosa and submucosa could be assimilated and maintained in an extract made from these tissues, such a substance would be invaluable in the treatment of ulcer. It has not been definitely proved if these desirable qualities are preserved in the extract which has been used at this Clinic. Furthermore, such a substance, when given orally, may be inert, although experimental work now being carried out gives evidence to the contrary.

In spite of the fact that some very encouraging results were noticeable in many of the cases in which patients were treated with the extract, no conclusive deductions can as yet be made. Further experimental work and a much longer period of observation are necessary before it can be assumed that this method of treatment has any merit whatsoever.

The treatment of peptic ulcer should take into con-

sideration not only the control of the aggressive mechanism of gastric acids, but, and equally important, the support of tissue defense as well.

When the specific factors utilized by duodenal tissues in preventing erosion by acid chyme are identified and isolated, there will undoubtedly be made available a substance of great usefulness in the treatment and in the prevention of recurrences of peptic ulcer.

## ABSTRACTS

DAVID, U. C.

*The Treatment of Carcinoma at the Rectosigmoid Junction by Obstruction Resection. S. G. and O. Vol. LIX, No. 3, Sept., 1934, pp. 491-495.*

The author proposes and describes an operation for carcinoma of the recto-sigmoid, less radical and less widely applicable than some others but having the advantage of removal of the growth, and adjacent lymphatics, with final restoration of continuity of the bowel. This operation is applicable in cases in which the only palpable metastases are immediately adjacent to the growth. In a limited number of cases in which it is not certain whether the lesion is benign or malignant this operation is applicable.

Assuming that in Trendelenberg position a mid-line incision has been made and the lesion found at the recto-sigmoid junction, the left leaf of the mesentery of the sigmoid and rectum is opened, and the incision carried forward at the lower end of the cul-de-sac between the bladder and the rectum to join another incision through the peritoneum on the medial surface of the mesosigmoid and mesorectum. The bowel is now pulled toward the mid-line, and the peritoneum dissected away from the mesentery by blunt dissection. The rectum is freed from the bladder by blunt dissection. The hand is now placed behind the superior hemorrhoidal vessels and the rectum freed from the hollow of the sacrum. After these maneuvers it is possible to lift the bowel containing the growth well out of the pelvis. At this point one should sum up the situation keeping in mind that it will be necessary (1) to remove the growth and its mesentery, (2) to have two or three inches of peritonealized bowel below the site of resection, (3) to cover the denuded bowel in the cul-de-sac, and (4) to have a long enough loop of sigmoid to swing around and sew to the peritoneum covered rectum for a future anastomosis. If any of these postulates are not feasible of performance, the operation proposed should be abandoned. If conditions are favorable it is easy to raise the peritoneum on either side of the cul-de-sac, and suture it to the peritoneum of the rectum. The mesentery of the bowel to be resected is divided in the usual way. The portion of the sigmoid just above the point of resection is placed in contact with the rectum just below the

point of resection and sutured to it. The parietal peritoneum is now separated from the anterior abdominal wall so that it falls without tension to the posterior parietal peritoneum. The anterior parietal peritoneum is now sutured to the posterior parietal peritoneum obliterating the cul-de-sac and extraperitonealizing the proposed site of resection. The obstructive resection as described by Rankin is now carried out, and the abdominal wall closed in layers. The clamps are removed on the following day, and a spur crushing clamp applied. If, after three months, the continuity of the bowel has not been established, the ends of the bowel, where they are not in union, are mobilized, and a three layer suture carried out.

The author has employed this technique eight times during the last ten years and has obtained very satisfactory results. Five figures accompany the article.

Nelson M. Percy, Chicago.

HUGH H. TROUT.

*The Treatment of Perforated "Peptic" Ulcers. Journal of the A. M. A., 104:1, Jan. 5, 1935.*

A study of forty-one cases of acute perforation of peptic ulcers treated by immediate operation is presented. The study was undertaken to determine:

1. The advisability of drainage after closure of the perforation;
2. The advisability of immediate gastro-enterostomy following closure of the perforation;
3. The best treatment of a gastric ulcer on the posterior wall that has perforated and is associated with hemorrhage.

The conclusions the author reaches are these:

1. Drainage following closure of a perforated ulcer should be avoided if possible;
2. Gastric suction through a nasal tube carried on continuously will decrease the necessity of immediate gastro-enterostomy. The less that is done outside of simple closure the better the patient's chances for recovery has been noted in the majority of instances, and
3. The combination of perforation with massive gastric hemorrhage of a posterior wall gastric ulcer is best treated by partial gastric resection.

Francis D. Murphy, Milwaukee.

## SECTION VII—*Surgery of the Lower Colon and Rectum*

### The Modern Proctologic Clinic\*

By

MARTIN J. SYNNOTT, M.A., M.D., F.A.C.P.  
NEW YORK CITY, NEW YORK

**P**ROCTOLOGY and procto-enterology constitute such a comparatively new specialty that there are not more than one hundred and fifty thoroughly qualified proctologists in the whole United States. Until quite recently our medical schools have given but little instruction in this subject, and even today the young men who graduate from our great medical centers receive no real training in the diagnosis of rectal diseases and their knowledge of the subject is surprisingly meager. A questionnaire (1), sent by H. Z. Hirshman in 1933 to every medical school in the United States, Canada, and the Philippines elicited the information that only twelve have adequate courses in proctology. Twenty-three schools have separate out-patient clinics but the Proctologic Department is combined with or is a division of that of Surgery; in fifty-three the teaching of proctology is combined with surgery and there is no separate out-patient clinic.

Very few hospitals, even in the largest cities, have proctologic clinics; for instance, in New York City there are only four such clinics officially listed and approved by the Academy of Medicine and the New York County Medical Society. In the suburban towns and smaller cities throughout the country the greatest ignorance of proctology prevails, and it is safe to say that not one percent of the medical practitioners of the United States own electrically lighted proctoscopes or would know how to use them if they did. The sigmoidoscope should, of course, be employed only by those specially trained in its use.

This situation is gradually being recognized, and many hospitals which formerly had no rectal clinics are now establishing them. Since it often happens that a new department, even though important, has difficulty in obtaining the floor space and equipment it needs and deserves, this paper is written with the idea of assisting those who may be about to start a proctologic department.

A decade or so ago, St. Mark's Hospital for Diseases of the Rectum, in London, had outgrown its quarters and the need for a new building was apparent. W. B. Gabriel, one of the attending surgeons, was delegated to draw up the plans. He devoted a year to this study with the result that the new building is a model of efficiency and convenience and is perfectly adapted for teaching. (12) The experiences of Mr. Gabriel

and his co-workers have done much to standardize the practice of proctology the world over, and the Out-Patients' Department of St. Mark's Hospital may safely be taken as a model. In reply to a recent letter inquiring whether or not any defects in the system of arrangement of the clinic had been discovered as a result of use, Mr. Gabriel writes:

"So far as the floor plan is concerned, I think the only defects which we have discovered in the process of time relate to the accommodation of patients in the Waiting Hall, which has proved too small for the large numbers which we now have to deal with; if we had our chance to do it again we should certainly have to make a larger Waiting Hall. The other little point I think relates to the actual Examination Room. We often have numbers of visitors and I think we want more room between the ends of the couches and the basins, so that nurses and visitors can circulate freely. Otherwise everything works as smoothly as ever." (2)

This is mentioned for the benefit of clinics where teaching is to be done or where many visitors are expected.

The examination room at St. Mark's has been copied by Bensuade in the Hôpital St. Antoine, in Paris, and also in our new Midtown Hospital in New York. (Fig. 2).

#### PLAN AND ARRANGEMENT OF CLINIC

Dressing room cubicles are essential and there should be two for each table so that during the examination of one patient another may be getting ready, thus preventing delay. There should also be convenient and separate lavatories and toilets for men and women. Men and women should not be taken into the examining room at the same time, for even though the cubicles ensure individual privacy the conversation between surgeon and patient is audible throughout the room and its nature is often such as to render the reason for this precaution apparent.

The Proctologic Examination Room should be as near as possible to both the Pathological Laboratory and the X-ray Department. The proximity of the former will ensure the prompt examination of smears of pus for gonococci and of feces for ameba, etc. The X-ray Department has much in common with the Examination Room and the attending proctologist will often wish to watch the flow of barium into the colon under the fluoroscope and the appearance of the bowel after evacuation, in cases of suspected cancer, diverti-

Submitted May 3, 1935.

Fig. 1

culitis (13), spastic colitis, ulcerative colitis, and numerous other conditions (14).

The examination room should be well lighted and well ventilated. In regard to the latter we may remark, however, that contrary to the popular and widespread opinion among general practitioners, proctology need not be in any sense offensive work.

There should be a high, book-keeper's desk, double, so that two men may write, standing one on each side; this saves time and space.

The examining tables may be simple wooden couches, 2x6 feet, where the patients may be placed flat on their backs for abdominal palpation, or in the left Sims' or knee-left shoulder position for sigmoidoscopy. A tilting table, such as the Buie or Hanes, is a welcome addition to a clinic, as with it the surgeon is able quickly to invert the patient in the ideal position for thorough and efficient examination and treatment. If these special expensive tables are not available, any straight table may be used, but the tilting table greatly reduces the irksomeness and weariness of a long examination in the knee-left shoulder position.

A small room adjoining the examination room is convenient for the taking of brief histories, as it reduces the crowd in the latter and saves time. A junior assistant may be assigned to this duty. Most patients are referred to a rectal clinic by their physicians on account of some definite complaint, therefore no lengthy histories or general physical examinations are necessary, at least on the first visit (15).

Patients, including the free clinic cases, should be treated with the utmost consideration and respect; this rule should be rigidly enforced at every proctologic clinic.

If the clinic is conducted as a philanthropy, the hours should, for economic reasons, be in the late afternoon (from 3 to 5:30) so that the wage earners may take advantage of them with minimum loss of time from work.

#### ESSENTIAL ARMAMENTARIUM

The essential for all rectal instruments is good illumination. The proximal light is preferable, be-

Fig. 1. Floor plan of examination room, Out Patient Department, St. Mark's Hospital, London, England.

cause the very small distal lights burn out easily and, as they are costly; this is an important consideration. In our opinion the best types of sigmoidoscopes are the Yeomans, the Cameron and the Lynch. Occasionally a sigmoidoscope with small diameter ( $\frac{5}{8}$  inch instead of the regulation  $\frac{7}{8}$  inch size) like the Lyon and Bartle, is of advantage especially in work with children or with patients where there is spasm or sharp angulation at the recto-sigmoid junction. The most practical anoscope for clinic purposes is the small Kelly ( $\frac{3}{4}$  inch diameter).

No one should attempt sigmoidoscopy who is not thoroughly familiar with the procedure, or fatal injury to the patient may result. Where the bowel passes over the promontory of the sacrum the mesentery is short, and when it is put on the stretch by the instrument the patient almost always complains of momentary pain. If any unusual difficulty is encountered or if the patient cries out with pain, the operator must be most cautious as there is danger of rupturing the bowel at this point. For the same reason the sigmoidoscope used should not be more than 10 inches long, as in all probability the end of a longer instrument is merely putting a loop of the sigmoid on the stretch and is not in the descending colon, as the inexperienced proctologist may be led to believe. We have seen two cases of ruptured sigmoid as a result of instrumentation, both accidents occurring in the practices of able and experienced proctologists. In one instance the rupture was not recognized at the time, and the patient died a few days later of septic peritonitis. In the second case, the rupture was due to an attempt to use a very long (16 inch) sigmoidoscope. This rupture was promptly recognized, an operation was performed within a few hours, and the patient made an uninterrupted recovery.

A good suction machine is almost indispensable, as with it pus, blood, mucus, and liquid feces may be quickly removed, allowing thorough inspection of the mucosa of the rectal ampulla and lower sigmoid. It also disposes of the smoke during electrocoagulation or surgical diathermy or during the use of the Paquelin cautery.

Another essential is a modern machine for electrocoagulation and cutting. Formerly many minor surgical procedures required hospitalization because of the danger of postoperative bleeding; these may now be done in the clinic, for there is little danger of hemorrhage after properly performed electrosurgery. Electrocoagulation or the electrical cutting current is very useful in the removal of polyps, and certain types of adenocarcinoma may be successfully treated by this method.

*Case.* Mrs. F. A. C., widow, aged 58, came to us first in 1931. She had noticed blood in stools since 1929, and had been treated for piles by several general practitioners. She finally consulted a general surgeon who recognized the true nature of her trouble and referred her to us for treatment. Examination revealed a fungoid, cauliflower neoplasm, the size of a large English walnut, on a sessile base  $\frac{2}{3}$  inch in diameter, located one inch above the anus on the anterior rectal wall. The growth bled easily and presented the adenomatous, polypoid appearance, with ragged ulcerating surface and dirty exudate, characteristic of malignancy. Blood Wassermann was negative. A biopsy

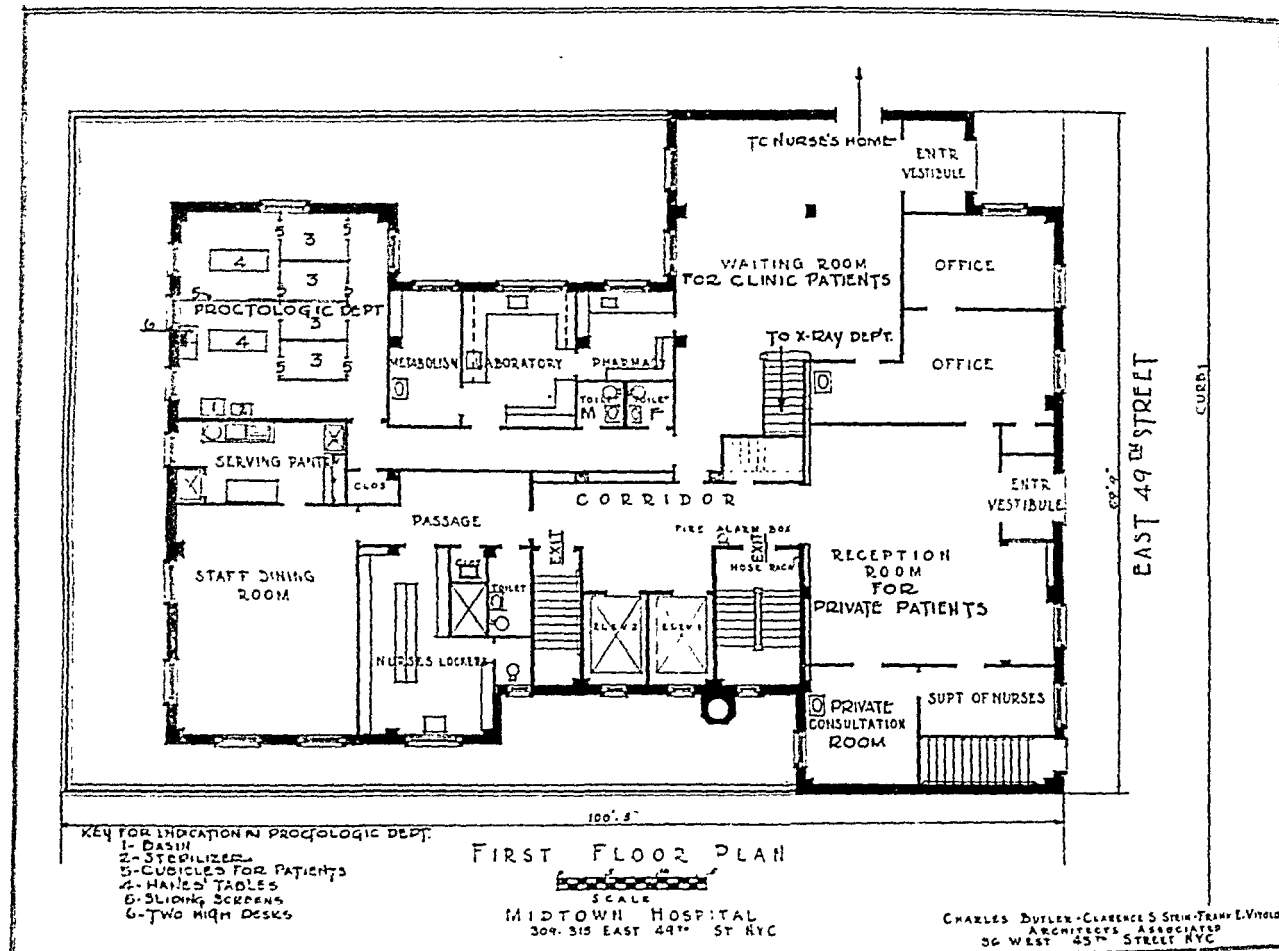

Fig. 2

was performed by Dr. Francis Carter Wood, who reported the tissue highly malignant, radio-resistant, inoperable adenocarcinoma. With the patient in the inverted position on the Hanes table, the anal sphincters were anesthetized with novocaine, and when they were relaxed, a large operating bakelite speculum  $1\frac{1}{4}$  inches in diameter was introduced and the growth was thoroughly coagulated. This procedure was repeated at intervals of a fortnight or so until 8 treatments in all had been given. No other measures were taken except to regulate the diet and keep the bowel movements soft. Bleeding ceased after the first treatment, the size of the growth rapidly declined, it finally disappeared, and the patient has been well ever since—a period of 3 years. The appearance of the mucosa is normal, the lumen of the bowel has been preserved, and no scar tissue can be felt on digital examination.

#### ANESTHESIA

In many clinic cases the anal conditions are so extremely painful that it is necessary to use an anesthetic of some kind before a thorough examination can be made. Painful fissures and ulcers, inflamed crypts, papillitis (16), pectenosis (3), and submucous abscesses often produce sphincteric anal spasm so intense that any digital or instrumental procedure is impossible. This is especially the case in highly neurasthenic or psychopathic individuals. For the relief of this condition novocaine or other local anesthetic is indicated, injected subcutaneously and into the sphincter muscles.

When silver nitrate is used in the anal region, the area is first anesthetized with local external applications of 4% cocaine or 10% metycaine solution, but cocaine is never used hypodermically.

Low spinal anesthesia is preferred for operative work such as hemorrhoidectomy, pectenotomy (4), and in fact for all surgical procedures about the anus and lower rectum. It has been proved by Gabriel and others at St. Mark's to be a safe and effective routine method (5). Lumbar puncture is sometimes followed by headache but this can be prevented in a large measure by the use of a fine needle in giving the spinal injection and by keeping the patient in the Trendelenburg position for 6 hours after the operation and not allowing the sitting posture for at least 24 hours.

We are not enthusiastic about caudal, sacral, or transsacral anesthesia, as it offers no apparent advantage over a low spinal and has a record of 20% complete or partial failures.

Local anesthetics—novocaine or anesthetic oils—may be used in operative procedures, but they sometimes alter the pathological picture, making it difficult to decide how much tissue should be removed; also the anesthesia is not always complete.

We hardly ever employ a general anesthetic because of the danger of postoperative chest complications and coughing. The vomiting and straining which frequently follow general anesthesia produce anal eversion.

prolapse of rectal mucosa with postoperative strangulation, or an annoying corona of edema, congestion or ulceration. The skin tabs which result prevent a perfect operative result and also delay convalescence.

All surgical procedures where an anesthetic is necessary will be facilitated if the patient is given a suitable dose of sodium amytal, nembutal, allonal, ortal sodium, alurate or phenobarbital the preceding night and a hypodermic injection of morphine with hyoscine one hour before the operation.

#### CONDITIONS TREATED IN A PROCTOLOGIC CLINIC

Among the many conditions which may be treated to advantage in the proctologic clinic are pruritus, amebiasis, and hemorrhoids. The clinic serves also a useful purpose in the prevention of cancer and in its early diagnosis while it is still operable.

#### PRURITUS

Many theories have been advanced concerning the etiology of pruritus. This seems to vary in different sections of the country: thus in New York comparatively few cases of fungus origin are seen, while in Richmond, Va., E. E. Terrell reports that 90% of his cases are primarily due to ringworm infection (6); on the other hand, R. A. Scarborough of San Francisco states that in 151 out of 152 cases of anal pruritus some definite local pathology was found on examination (7).

The cases of pruritus seen in our clinic during the past 5 years can be divided into four groups, according to the etiological factors, as follows:

1. *Local anal pathology.* The *anal conditions* which most frequently serve as exciting causes of pruritus are cryptitis, papillitis, pectenosis, fissure, ulcer, fistula, pin worms, submucous abscess, skin tabs from old thrombotic external hemorrhoids, prolapsing internal piles, leakage from an atonic anus due to tabes or pederasty or an incompetent sphincter following surgery or trauma. Certain of these conditions, such as painful ulcers and fissures, may be treated by palliative measures, but in many cases surgery is necessary.

2. *Intestinal toxemia* AVGQ. Under this heading we include the toxic colon (18) and infectious proctitis due to the streptococcus or the gonococcus. Pruritus may result from the toxins which are absorbed by the lymphatics and enter the connective tissue perianal spaces, causing an excitation of the sensory nerves—neurodermatitis. Such cases are helped by colon stasis regimen, bland non-roughage diet, and colon irrigations; in fact colon drainage by effective lavage is definitely beneficial. In pruritus complicating severe intestinal toxemia, duodenobiliary drainage at regular intervals, given according to the technique of B. B. Vincent Lyon (8) is of great value. This treatment will relieve the associated biliary and intestinal stasis, the chronic low grade infection of the gall tract, and the duodenitis (19).

3. *Epidermophytosis, trichophyton or other fungus infection.* The presence of fungus infection should be suspected in every case of pruritus and examination of the feet and finger nails for evidence of it is always indicated. If this is found, treatment with mercury, mercurochrome or salicylic acid according to the routine described by Terrell (6) is usually effective. Fungus antigens are helpful in obstinate cases.

4. *Diabetes.* This is a rare factor in pruritus, but it does occasionally occur. Therefore every patient, especially those who are middle aged or obese should have urinalysis and perhaps a blood sugar determination or a sugar tolerance test.

For the symptomatic relief of the itching in pruritus—irrespective of cause—we have had exceptionally good results from the injection of benacol (9), anacaine (10) or one of the other similar anesthetic oils now on the market. These oil preparations owe their efficacy to the fact that they are slowly absorbed in the tissues and therefore their effect is prolonged—the anesthesia lasting from 3 to 7 days.

We advise the violet ray or alpine sun lamp in all obstinate pruritus cases, but in our clinic the X-ray is not used. This latter method devitalizes the skin and causes connective tissue growth with thickening, hypertrophy, and radiation dermatitis, making the last state of the patient worse than the first.

Personal hygiene is always stressed: pruritic patients are instructed to take daily hot baths and to wash the anal region with a good soap and hot water after each bowel movement. If the pruritic area is unduly hairy it is shaved; certain patients do not begin to improve until this is done.

#### AMEBIASIS

Since the Chicago epidemic in the summer of 1933, many cases of amebic dysentery have been reported in various sections of the country. There are undoubtedly numerous unrecognized ambulatory cases, and physicians in gastro-intestinal and proctologic clinics should therefore be particularly alert and vigilant in recognizing and diagnosing the condition. In the subacute or "walking" types the usual complaints are blood in the stools, with rectal pain or tenesmus and tenderness along the transverse colon, the *pars descendens* or sigmoid, together with malaise and loss of working power. Prompt diagnosis and appropriate intensive treatment often produce spectacular results.

*Case.* Woman, secretary, unmarried, aged 26, living in a suburb from which she commuted daily, was referred by her family physician to the Midtown Hospital for a barium enema and plates of her colon. She had been having repeated attacks of relaxed bowel movements with occasional frank blood, and persistent rectal pain and tenesmus, for 10 weeks. The treatment had consisted of various medications, regulation of diet, etc., but no proctologic examination had been made. Our roentgenologist, Redford K. Johnson, before giving the barium enema, decided that sigmoidoscopy was indicated and brought her into the proctologic clinic. The rectum contained much mucus and feces streaked with blood. The mucosa showed the petechial spots characteristic of amebic infection; these were easily traumatized and bled at the slightest touch. There was one small serpiginous ulceration. A small, dull, spoon curette removed some of the infected material which, on examination, showed numerous endamebal histolytical. The patient was immediately given an intramuscular injection of emetine hydrochloride and a course of intensive treatment was started. She responded favorably and made an uninterrupted recovery.

#### HEMORRHOIDS

It requires a long clinical experience to decide upon the proper method of treating hemorrhoids. The three methods used in our clinic are:

1. *Injection.* This is employed only in cases of uncomplicated internal hemorrhoids—those which are soft and bleed easily. We use a mixture of 5% phenol

in oil which, when properly injected, gives most satisfactory results. Even cases so severe as to appear, at first sight, unsuited to this method often respond favorably.

2. *Operation.* This is necessary if the piles are large and prolapsed. The Buie technique is followed with the exception of position: we adopt the exaggerated lithotomy position, whereas Buie places the patient prone, face down, with an elevated bridge under the pelvis.

3. *Expectant.* By this is meant rest in bed, hot baths, local sedative or astringent applications, non-roughage diet and colon regimen. It is indicated in the case of feeble or elderly persons who are debilitated or who have weak hearts.

We make it a rule never to operate in the presence of strangulation, perianal edema, ulceration or sloughing. In such cases expectant treatment alone is indicated, with the possibility of operation later. Failure to observe this rule may result in grave complications, septicemia and death.

*Case.* Young man, chauffeur, came for advice about "piles." Examination showed large, prolapsing, internal hemorrhoids, not inflamed. Operation was advised. Ten days later he returned in great discomfort, reporting that his employer had sent him to a general hospital where the attending surgeon had turned him over to an interne for operation. He had been discharged "cured" on the fourth postoperative day. We examined him again and found an enormous perianal corona of edema due to prolapsing, constricted internal hemorrhoids and rectal mucosa. We advised him to return to the hospital for further care, which he did. This time an assistant attending surgeon, not a proctologist, decided to operate at once instead of ordering palliative treatment; i.e., hot sitz baths, local sedative moist dressings, rest in bed and suitable diet. The anus was divulsed and an attempt was made to excise the prolapsing edematous and highly inflamed tissue. The patient developed fever, rapidly became septic, the blood culture showed streptococci, and he died a few days later of septicemia.

#### CANCER. EARLY DIAGNOSIS AND PREVENTION

The greatest object in proctology today is to facilitate the diagnosis of malignant growths and to recognize pre-cancerous conditions, such as adenoma and polyp, thus permitting cancer to be attacked at an early stage.

No treatment of hemorrhoids, operative or otherwise, should be undertaken without a thorough and satisfactory examination of the lower sigmoid, anus and rectum.

The history of most clinic patients who come to us with advanced carcinoma is one of neglect and delay; a history of bleeding for 6 to 12 or even 18 months; a diagnosis of "piles" by the family physician, and treatment by suppositories and ointments. Of the new cases of cancer seen at proctologic clinics, 40% are inoperable, and 20% give a history of hemorrhoidectomy mistakenly performed without preliminary sigmoidoscopy within 6 months or a year. The general practitioner must learn to recognize the symptoms of rectal cancer before the growth has become inoperable. A history of bleeding from the rectum or of blood streaked stools, rectal irritability, mucoid discharge, or alteration in the regular habits of defecation should

always suggest a thorough proctologic examination by a qualified specialist equipped with the necessary, properly lighted instruments.

The hard nodules of an early anal epithelioma, which bleed easily after a bowel movement, are sometimes mistaken by general surgeons inexperienced in proctology for "bleeding piles," and ill-advised surgical procedures undertaken.

*Case.* Women, aged 42, married and mother of one child, came to our clinic with the following history. Four weeks previously she had had a Whitehead operation for piles, performed by a general surgeon. Before this she had suffered from anal pain and spasm, with occasional bleeding for 9 months. She did well immediately after the operation, but a week later the surgeon informed her husband that the laboratory sections of the tissue removed indicated malignancy. Examination showed an evident recurrence of the growth, as there were numerous hard nodules in the line of the incision. A proctologic surgeon was called in consultation and a perineal excision of the anus and rectum performed. She made an excellent post-operative recovery and remained in good health for a year, when metastases suddenly developed in the brain and she died.

Polyps are not uncommon in young children and often cause bleeding. Children submit readily, as a rule, to rectal examinations if their confidence and co-operation are secured, and sigmoidoscopy is relatively easier in a child than in the average adult.

*Case.* Boy, aged 6, was brought to us by his mother with a history of bright blood in his stools for 6 months. She had taken him to several pediatric clinics, where medicine and special diets were prescribed for "hemorrhagic colitis," but no rectal examination had been suggested or performed. Sigmoidoscopy showed a bleeding polyp on a pedunculated base,  $\frac{3}{4}$  inch in length, in his rectum. A Yeomans electrocoagulating snare was passed about it, through a bakelite speculum, and the growth removed. The patient felt no pain and has been without symptoms for a year.

#### CONCLUSIONS

In conclusion, it may be stated that there are no short cuts into the field of proctology. A thorough knowledge of gastro-enterology is a necessary prerequisite and familiarity with the pelvic and perineal anatomy is essential. Sound judgment in diagnosis and treatment is acquired only after extensive experience, and to qualify as a specialist many years of painstaking study, travel and observation are required. The functions and mechanics of the muscles, glands, nerves and blood vessels in health and disease must be understood.

Preliminary training in general surgery is most desirable, if not obligatory. It is *not* necessary, however, for every proctologist to feel that he must be qualified to perform abdomino-perineal excision for carcinoma. This operation had better be left to those surgeons—few in number—who, as a result of experience, opportunity and training have acquired the skill, technique, dexterity, speed, team work, and special knowledge essential to success and to a low operative mortality. This includes the careful and intelligent pre-operative preparation of the patient and the after treatment.

## SECTION VIII—Editorial

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### THE COMMON PATHOGENESIS OF TERMINAL ILEITIS, IDIOPATHIC ULCERATIVE COLITIS AND BACILLARY DYSENTERY

FELSEN'S recent alignment of regional ileitis with bacillary dysentery (*A. J. D. D. and N.*, 1-11, Jan., 1935), leads one to reconsider the trend of the last four or five years towards the inclusion of chronic bacillary dysentery and ulcerative colitis in one class. Because of the resemblance of these two conditions perhaps the dysentery bacillus is being unduly neglected.

If we assume that these two diseases are one and the same, still there are many patients with the clinical picture of idiopathic ulcerative colitis who give positive serum agglutination reactions in high dilution with one or other strain of the dysentery bacillus. And that these strains are specific is indicated by the marked reaction to one strain and the almost complete failure of reaction to any of the other strains. The several dysentery strains would seem to be almost as specific as the strains of the pneumococcus.

In recent years, practically all of our adult cases that have reacted have given sharp agglutination reactions in high dilution with one strain only, either the Flexner or the Mt. Desert strain, mostly the latter, and only slight reactions with all the other strains. The commercial serums obtainable do not represent the Mt. Desert strain. Yet when the agglutination reactions are highly specific for a particular strain, obviously any serum or vaccine used must also be specific, and the serum or vaccine from any other strain or strains can be nothing else than useless. It is because of an occasional apparent striking result from the use of vaccines that I open the subject once more.

In order therefore to help toward conclusions as to the relation of chronic bacillary dysentery, ulcerative colitis and regional ileitis, and to appraise the therapeutic value of serum or vaccine in these chronic cases, may we urge that those clinicians and bacteriologists who are making observations test all cases of ulcerative colitis and regional ileitis for agglutination reactions with the various strains of the dysentery bacillus? May we urge further that, where such are

positive, they administer a stock vaccine of the specific strain or a serum that represents it?

In some of our clinics this has not been done, yet, until such tests and treatments are carried out consistently through the years, we cannot really establish the relation of the diseases, or assess the therapeutic value of serum or vaccine; and it may be that we are missing a valuable therapeutic help. Naturally, judgment of results will have to be reserved, for in any chronic case there cannot be the dramatic effects obtained in an acute case.

At this stage, might we not properly reclassify our cases into: Ulcerative colitis with dysentery agglutinations and Ulcerative colitis without dysentery agglutinations; and, Regional ileitis with dysentery agglutinations and Regional ileitis without dysentery agglutinations?

Walter A. Bastedo, New York City.

### NEW YORK CITY ACTIVE FOR THE AMERICAN BOARD OF GASTROENTEROLOGY

THE medical men of the city of New York comprise approximately one-twentieth of the membership of the American Medical Association. It has two active gastroenterological associations, one local to New York City, the New York City Gastroenterological Association, and the other, a newly formed national organization, the National Society for the Advancement of Gastroenterology. Both have gone on record and are actively interested in the establishment of the American Board of Gastroenterology. The resolutions from them sent to the House of Delegates of the American Medical Association are as follows:  
Adopted Jan. 31, 1935:

We, the New York Gastroenterological Association, all of whom are members of the American Medical Association in good standing, respectfully ask for favorable action on the recognition of the American Board of Gastroenterology. For eighteen years we have had a Section in the subject in the American Medical Association, which Section has stimulated an interest in the diagnostic and medical aspects of abdominal work and done much in advancing American Medicine. In this Section the workers in this field of medicine have

given of their time and activities in the constantly multiplying aspects of the subject. To encourage these, we feel that this field of work should be recognized by certification by the already established American Board of Gastroenterology.

Adopted Feb. 6, 1935:

WHEREAS, the members of the National Society for the Advancement of Gastroenterology assembled Feb. 6, 1935, which organization is committed to the advancement of gastroenterology for the benefit of American medicine, and

WHEREAS, since the establishment of the Section of Gastroenterology and Proctology eighteen years ago in the American Medical Association it has done much in stimulating a higher quality of diagnostic and medical abdominal work in the profession in this country, and

WHEREAS, most of the advances made have been accomplished by those who have been working intensively in this field of work and freely given of their work to American medicine, and

WHEREAS, the members of this organization are all of them members of the American Medical Association in good standing,

BE IT RESOLVED, that we respectfully request our parent organization, the American Medical Association, to certify this field of work by authorization of the American Board of Gastroenterology to stimulate still better work in the subject on the part of the profession and request also that we as a national organization be given representation on the Board of Gastroenterology with the Section of the American Medical Association and the American Gastroenterological Association.

It is hoped that these resolutions will assist in the establishment of the American Board of Gastroenterology so that this field of medical work can take its place in certification with the departments of ophthalmology, otolaryngology, obstetrics and gynecology, dermatology and syphilology, pediatrics, psychiatry and neurology and radiology.

Anthony Bassler, New York City.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

*Diet Manual, St. Mary's Hospital, Rochester, Minn.* By Sister Mary Victor, R.N., B.S., Director of the Department of Nutrition, St. Mary's Hospital; Published by the Institution; Second Edition, 1935, 191 pages, supplemented by numerous graphs and tables.

THE author is recognized as one of the outstanding clinical dietitians and nutrition experts in the world. In her book she has performed a distinct service to hospitals and sanatoria and even to internists, generally, by rendering available the specific dieto-therapeutic regimes which have made distinguished the department which she heads at the famed St. Mary's Hospital, the "helping hand and workshop" of the Staff members at the Mayo Clinic.

Although Sister Mary Victor's book is classed as "Second Edition," the reviewer is not familiar with the "first edition," unless such term could be applied to the numerically limited and rather preciously hoarded, paper-covered "Diet Lists" of which the visitor to the Mayo Clinic occasionally caught a fleeting glimpse—and vainly endeavored to borrow, beg, buy or purloin a copy!

Evidently, in a certain degree, the economic depression affected St. Mary's Hospital. While we commiserate with the management of that Institution, simultaneously, we rejoice that the consequent lessening of routine labor made possible a "breathing spell" for a very much overburdened Sister and permitted her to set forth, in orderly sequence and in suitable form, those procedures to which she has given so many thoughtful and arduous years. The resulting book is eminently satisfactory for what it purports to be: "simply a compilation of diet procedures employed in the treatment of disease by the Medical Staff of St. Mary's Hospital and the Mayo Clinic." However, Sister Mary Victor is rather more than modest when

she states that her book is "simply a compilation." As one peruses Part 1 ("The Optimum Diet"), Part 2 (Therapeutic Diet for Adults, with its twelve sections), Part 3 (Infant and Child Feeding), Part 4 (Instruction Sheets) and Part 5 (An "Appendix" rich in details respecting various height, weight, age tables, lists of food values, qualitative, nutritive, and chemical "dissection" of specific foods and diets, etc.), he discovers that the Author has contributed much of her own knowledge and ingenuity to make clinically workable the demands—both investigative and therapeutic—of an exacting, ever-revising, inquisitive group of clinicians and researchers. In these days of nutritional flux, one wonders when the Director of a Department of Diets in a Clinic whose attitude is almost as much in the field of research as in medical and dietetic therapy, finds conditions sufficiently "static" to admit of having *any* routine or set scheme of dietetics in her plant. Certainly, one so placed, often must needs herself resort to the principles of the ketogenic diet for the resultant headaches!

Without going into intricate analysis of the "compilation" presented by Sister Mary Victor—really an encyclopedia of what is most advanced and proved in the modern conception of diet as a means of treating common or unusual ailments—one cheerfully commends the *rationale* and clarity of the diets set forth for the management of constipation, weight reduction, cardiovascular and renal disease, diabetes (with its excellent recipes), peptic ulcer, ailments of the colon, (particularly the ulcerative affections), arthritis, the ketoses, postoperative conditions, and those suited to ailments affecting infants and children.

The methods of presentation are simple and logical. Diets are exhibited to meet all possible variations in given affections and, what especially is satisfying, is that more than an ordinary effort has been made to

offer selections of foods which readily are available in most communities, are economical and are palatable.

"Instruction Sheets" for patients' use are refreshingly simple in that they state definitely what patients may have and what not, thus affording those employing them such choices as may suit the purse, residence or social condition. Faddism and the exhibition of "queer," "patented," "foreign," expensive or difficult-to-secure foods rarely. Whether patients remain for treatment at Rochester or, after being set on the proper trail, they continue dietotherapy at home, the very sensible instruction-sheets presented by Sister Mary Victor, if adhered to, cannot fail to prove helpful.

The Author is to be congratulated upon her accur-

ate, intelligent and painstaking work. Without reservations, her book is recommended to dietitians in hospitals and sanatoria as the most useful compendium of its type yet published. No institution which assumes to exhibit modern dietotherapy can claim completeness unless it has available for daily use Sister Mary Victor's book. Nurses' Training Schools, nurses and physicians in practice will find the work invaluable.

The volume is attractively printed and substantially bound. Evidently it is printed privately, inasmuch as it carries no publisher's imprint other than "St. Mary's Hospital, Rochester, Minn." Presumably the book can be purchased (price not stated) by direct application to the Hospital which sponsors it.

Frank Smithies.

## SECTION XI—*Societies, Programs and Proceedings*

### FINAL PROGRAM OF THE THIRTY-EIGHTH ANNUAL MEETING OF THE American Gastro-Enterological Association

To be held at

ATLANTIC CITY

MONDAY AND TUESDAY, JUNE 10 AND 11, 1935

HEADQUARTERS AND ALL SESSIONS AT  
HOTEL TRAYMORE

MONDAY, JUNE 10, 1935

MORNING SESSION, 9:00 A. M.

Memorial Address on Dr. Albert Bernheim  
Dr. David Riesman, Philadelphia.

Presidential Address  
Dr. B. B. Vincent Lyon, Philadelphia.

1. "Studies on Crystalline Vitamin B—Observations in Diabetes."

Dr. Martin G. Vorhaus, New York, N. Y.  
R. R. Williams, M.S. (by invitation),  
New York, N. Y.  
R. E. Waterman, B.S. (by invitation),  
New York, N. Y.

DISCUSSION to be opened by  
Dr. Joseph T. Beardwood, Jr., (by invitation), Philadelphia, Pa.  
Dr. J. Earl Thomas, Philadelphia, Pa.

2. "Influence on Carbohydrate Metabolism of Experimentally Induced Hepatic Changes."

Dr. T. L. Althausen, San Francisco, Calif.  
B. Blomquist, M.A., (by invitation),  
San Francisco, Calif.

DISCUSSION to be opened by  
Dr. Arnold R. Rich, (by invitation),  
Baltimore, Md.  
Dr. Frank C. Mann, Rochester, Minn.

3. "Gastro-intestinal Manifestations of Hyperinsulinism."

Dr. Seale Harris, Birmingham, Alabama.  
DISCUSSION to be opened by  
Dr. Julius Friedenwald, Baltimore, Md.  
Dr. Frank Smithies, Chicago, Ill.

4. "Present Conceptions of Calcium Metabolism."

Dr. David L. Thomson, (by invitation),  
Montreal, Canada.

DISCUSSION to be opened by  
Dr. Lay Martin, Baltimore, Md.  
Dr. A. C. Ivy, Chicago, Ill.

11:30 A. M.

5. THE ALVAREZ LECTURE—(Founded in 1928 by Dr. Frank Smithies).

Dr. Lewellys F. Barker, Baltimore, Md.

LUNCHEON

AFTERNOON SESSION

2 P. M.

6. "Abdominal Pain as a Misleading Symptom of Spinal Cord Lesions."

Dr. Everett D. Kiefer, Boston, Mass.

DISCUSSION to be opened by  
Dr. Howard F. Shattuck, New York, N. Y.

Dr. Gilbert Horrax, (by invitation),  
Boston, Mass.

7. "Experimental Studies of Chronic Visceral Infection in Relation to Gastro-Enterological Problems."

Dr. Martin E. Rehfuess, Philadelphia, Pa.

Dr. Guy M. Nelson, (by invitation),  
Philadelphia, Pa.

DISCUSSION to be opened by

Dr. Ernest H. Gaither, Baltimore, Md.

Dr. W. L. Palmer, Chicago, Ill.

8. "The Present Status of Colon Bacillus Vaccine Therapy."

Dr. John G. Mateer, Detroit, Michigan.

Dr. James I. Baltz, Dr. James Fitzgerald and

Dr. Harris L. Woodburne, (by invitation),  
Detroit, Michigan.

DISCUSSION to be opened by

Dr. Sara M. Jordan, Boston, Mass.

Dr. Leon Schiff, Cincinnati, Ohio.

9. "Serum Lipase: Its Diagnostic Value."

Dr. Mandred W. Comfort, Rochester, Minn.

DISCUSSION to be opened by

Dr. Daniel N. Silverman, New Orleans, La.

Dr. Arthur C. Clasen, Kansas City, Mo.

10. "Report of Enzyme Committee."

Dr. A. H. Aaron, Chairman

Dr. H. L. Bockus

Dr. Mandred W. Comfort

Dr. Burrill B. Crohn

Dr. A. C. Ivy

Dr. Victor C. Myers

Dr. T. L. Althausen

Dr. R. H. M. Hardisty

EXECUTIVE SESSION

(Associate members are requested not to attend).

ANNUAL DINNER, 7:30 P. M.

HOTEL TRAYMORE, ATLANTIC CITY,  
N. J.

*Guests of Honor*

"Historical Review of Gastric Surgery"

DR. DEAN LEWIS

Professor of Surgery, Johns Hopkins University, Baltimore, Md.

"Medicine in the Eighteenth Century as seen in the Pictures of William Hogarth."

## SECTION XII—"The Clinic"

### An Unusual Case of Primary Actinomycosis Involving the Mesentery of the Small Intestine\*

By

C. J. TIDMARSH, M.A., M.D., F.R.C.P.(C).  
BOSTON, MASSACHUSETTS

A REVIEW of the literature for the past ten years, including the 670 cases reported by Sanford and Voelker in 1925, reveals the fact that primary actinomycosis of the mesentery must be extremely rare. Sanford and Voelker do not mention a single case where the mesentery primarily was involved.

In regard to the mode of infection, most authors agree that very often spore forms from vegetation are introduced into the soft tissues as a result of injury by a foreign body. In the case reported below, it is interesting to note that at operation Dr. Lahey remarked that the finding indicated perforation of the small intestine by a foreign body, and on questioning the patient later she distinctly remembers having choked on a fish bone several weeks prior to the onset of her present illness.

Fig. 1. Actinomycotic colonies embedded in inflammatory tissue of mesentery. Note typical ray formation. X175.

\*From the Department of Gastro-Enterology,  
Lahey Clinic, Boston, Mass.  
Submitted March 25, 1935.

## CASE REPORT

Mrs. E. T. H., housewife, age 60, was admitted to the Lahey Clinic, October 10, 1934, with complaints of: (a) full feeling in abdomen: (b) soreness left abdomen.

Present illness commenced on the 3rd of September, 1934, while enroute to Honolulu, with general malaise, loss of appetite, nausea, full feeling in abdomen, soreness in left abdomen especially when lying on left side. The ship doctor ordered salts and an enema which were partially effectual but gave no relief. During the next two days the symptoms became more severe, especially the abdominal pain, fullness and nausea. Further laxatives and enemas were not effectual. On arrival at Honolulu, the patient was admitted to the Tripler General Hospital. The following is an abstract of the hospital report:

"Admitted September 7, temperature 101°, pulse 116, respiration 22, white blood count 18,400, urine negative, blood pressure 112/64. There is a large mass the size of a coconut in the left lower abdomen—tense, not hard, tender and fixed. General physical examination otherwise negative. Daily enemas were effectual and these with turpentine stupes resulted in gradual softening of the mass with decrease in size,—mass now movable. On September 12, pelvic examination was negative with the exception of a small, cervical polyp.

Barium enema—colon essentially negative except the descending colon appears displaced toward the mid-line. Repeated the next day with same conclusion. By September 20, the temperature and white count were normal, bowels were regular and the mass estimated to be one-fifth of its size on admission. Total weight-loss ten pounds. Discharged. Final diagnosis: 1. Tumor, left lower quadrant—type undetermined. 2. Partial intestinal obstruction due to (1). 3. Cervical polyp."

Improvement continued during the return voyage. The enemas and laxatives were continued for relief of the full feeling. The patient gained four pounds. Now feels stronger but still has abdominal discomfort.

General physical examination at the Lahey Clinic essentially was negative with the exception of a small mass in the left lower quadrant towards the mid line and the cervical polyp. Laboratory examinations—urinalysis, blood count, non-protein nitrogen, bilirubin and Hinton—all normal. Gastric analysis (Ewald meal) free acid 0, total 12. X-rays of stomach and colon were negative for organic disease.

Personal and family histories irrelevant.

In view of patient's age, history achlorhydria and presence of palpable mass, exploration was advised.

Exploratory operation.—Dr. Lahey, October 26, 1934. The liver, gall bladder, stomach, pelvic organs and

kidneys were found to be normal. The colon was normal. Adhesions in the sigmoid area and long adhesions from the small bowel over to the left lateral wall. A loop of small bowel was found to be quite reddened, with inflammatory reaction, and in the mesentery there was a hard mass, probably inflammatory, about the size of a walnut. After the mass was carefully dissected away from the small intestine, there was found at the base where it joined the small bowel, an opening from the bowel into the solid mass.

The site of injection was invaginated by two purse string sutures. Careful search throughout the abdomen revealed nothing further except the adhesions referred to above. Routine closure. The patient made an uneventful postoperative recovery.

By courtesy of Dr. Shields Warren, pathologist to the New England Deaconess Hospital, the following pathological report is given: "Several sections of the mass show irregular foci measuring as much as 1 cm. in diameter in which there is

## FOR PEPTIC ULCER

### A REVOLUTIONARY TREATMENT

*Peptic ulcer becomes symptom-free on the*  
**LAROSTIDIN TREATMENT**  
*One daily injection for about 24 days*

**Larostidin Ampuls, 5cc . . . Cartons of 6**  
*4 boxes constitute one complete treatment*

*After 5 days . . .* Pain usually disappears and does not recur. Nausea, vomiting, hyperacidity, and flatulence are relieved.

*After 10 days . . .* Normal diet well tolerated. Appetite improves. There is consequent gain in weight, general systemic improvement, and vastly improved mental outlook.

*After 24 days . . .* There is usually remission of all symptoms, viz.: food intolerance, gastric pain, and hyperacidity. Normal emptying time, normal peristalsis and absence of spasticity are evidenced.

● Drs. VOLINI and McLAUGHLIN, *Medical Record*, April 17th, 1935 report: "The parenteral use of histidine monohydrochloride (larostidin, Roche) produces rapid clinical improvement in patients with gastroduodenal ulcer upon liberal diets and while ambulatory. Pain, vomiting, hypersecretion and retention quickly improve or disappear. Appetite and weight increase is noted."

● BULMER, in reporting his results in 52 cases of peptic ulcer (*The Lancet*, Dec. 8, 1934) emphasized the fact that the Larostidin treatment is better than the older methods—alkalies, feedings, etc.—in bringing about complete subsidence of symptoms, and that these results are easily achieved with ambulatory management. Dr. Bulmer's paper was abstracted in the *Journal of the American Medical Association*, February 23, 1935, page 690.

**HOFFMANN • LA ROCHE • INC • NUTLEY • NEW JERSEY**

great increase in collagenous tissue. Throughout these foci are many regions of intense infiltration by lymphocytes and plasma cells. In some places, many hemosiderin-laden phagocytes are present in among the lymphocytes, and in a few foci small abscesses, with many polymorphonuclear leucocytes, are seen surrounded by a broad zone of plasma cell and lymphocytic infiltration. In the center of one such abscess are several clumps of actinomycetes with a cen-

tral mycelium and peripheral radially arranged club-like structures (Fig. 1). In the tissue surrounding the abscesses are some capillaries lined by swollen epithelial cells and in some places are seen fat laden phagocytes."

It is now nearly four months since operation and the patient reports that she is perfectly well and has no symptoms of any kind.

## CELLU

### One-Three-Three Flour

*Specifically made for diets requiring a bread substitute of low available carbohydrate value*

#### Pleasant to Use

Cellu One-Three-Three Flour is carefully compounded to insure a very tasty muffin and one which is easily and successfully prepared. The flour is put up in envelopes containing a weighed portion of 45 grams, this amount being sufficient for one baking of six muffins when combined with two eggs. Patients do not tire of this bread substitute because of its pleasing flavor.

#### Ingredient Content

The chief ingredients are pulverized washed bran, starch, vegetable fat, leavening, salt, and India Gum.

*We Would Like to Send You a Sample to Try*

#### Food Value

The calculated available food value of each finished muffin is: Fat, 3 grams; Protein, 3 grams; available Carbohydrate, 1 gram.

# Incomplete Intestinal Obstruction Due to Shortened Ligament of Treitz

By

JOSEPH STEIN, M.D.  
HAWTHORNE, NEW YORK

MRS. M. L. was referred on May 1, 1934, by Dr. John R. Evers for X-ray gastro-intestinal study. Her main complaints were vomiting after every meal since January and loss of weight. The vomiting came on either immediately after meals or within two hours. This patient has been previously X-rayed elsewhere with essentially negative findings reported.

The following report of my findings was sent to Dr. Evers on May 2, 1934: 'Fluoroscopic examination of the esophagus and stomach reveals momentary spasm of the cardia which, however, opens and allows the barium meal to enter the stomach; the esophagus is otherwise normal in contour. The duodenal cap is likewise momentarily spastic but soon fills out. The stomach is normal in outline.

The distal half of the descending portion of the duodenum is dilated but not permanently so as in a diverticulum. Retroperistaltic waves are observed beginning at the distal end of the descending portion of the duodenum; they are very marked. The contrast meal is reversed in direction and the reverse waves are soon observed involving the stomach right through the cardiac end filling up the esophagus in reverse direction.

X-ray films bear out fluoroscopic findings.

**Conclusions:** I consulted about this phenomenon with Dr. S. Goldfarb, chief of the X-ray intestinal division at Mt. Sinai Hospital. He advises me such a condition may be due to any of the following causes:

1. Shortened ligament of Treitz.
  2. Enlarged glands pressing against the duodenum.
  3. Mesenteric vessels partially occluding duodenum.
  4. Functional and unknown causes.
- I would suggest that you be guided accordingly."

The patient was admitted to St. Agnes Hospital, White Plains, N. Y., on May 16, 1934. The hospital records follow:

## PERSONAL HISTORY

**Chief complaints:** 1. Vomiting after every meal and pains in the abdomen following ingestion of food or water for 5-6 months.

Submitted February 20, 1935.

2. Loss of 20 pounds in weight last 6-8 months. Appetite is good but is unable to keep food down.

3. Attacks of "indigestion" with pain in the abdomen and occasional fainting during the last 20 years at irregular intervals according to the patient by eating certain foods, as corn and bananas.

**Childhood:** Chicken pox, mumps, measles and nose bleeds often.

**Surgical:** Appendectomy and hysterectomy 7 years ago. Thyroidectomy January, 1934.

**Veneral:** Denied.

**Menstruation:** 16x28x5 always regular until about 9 years ago when patient had menorrhagia (18 days) and noticed intraabdominal tumor.

**Obstetrical:** No children, no miscarriages.

## PHYSICAL EXAMINATION

**Head and Neck:** Eyes react to light and accommodation. E.N.T. negative.

**Chest:** Normal contour and expansion. Lungs clear throughout. Heart apparently normal.

**Abdomen:** Slight distension and tenderness throughout and especially in epigastrium, no palpable mass. Pelvic not done.

**Extremities:** No edema, reflexes normal.

## Laboratory Findings:

1. Urine: Negative except for very faint trace of albumin.

2. Blood: Hemoglobin 87; red blood count 4,190,000; leucocytes 15,900; small lymphocytes 10; polys 90.

## May 16, 1934: From Progress Record.

Thirty-five year old white female admitted with a long history of vomiting and abdominal pains following several operations.

**Impression:** Partial intestinal obstruction and post-operative adhesions.—Dr. Byers.

May 17, 1934. Operative procedure and findings by Dr. Evers.

Rather marked adhesions of the omentum and 2 loops of small intestine along prior sub-umbilical wound. There were several peri-sigmoidal and pericecal filamentous adhesions and one loop of small intestine was angulated on itself by reason of adhesion; one apparently omental variant was found between the fundus of the gall-bladder

and the second portion of the duodenum and several small contracted adhesions overlying the second portion of the duodenum. At the ligament of Treitz there was a dense contracted band causing sharp angulation of the beginning of the jejunum. Previous appendectomy and hysterectomy had been done.

Upper midline incision. Freeing of gall bladder adhesions, mobilization of the ligament of Treitz by transverse incision of the contracted band, which completely relieved the angulation and allowed the previously distended duodenum immediately to collapse. 100 cc. of "amphetin" were instilled and routine closure of the belly wall without drainage.

**Preoperative Diagnosis:** Partial duodenal occlusion due to shortened Ligament of Treitz.

**Postoperative Diagnosis:** Marked omental and intestinal adhesions and short fibrous Ligament of Treitz.

## Continuation of Progress Record:

May 17, 1934: Laparotomy done and adhesions freed, postoperative condition satisfactory.—Dr. Byers.

May 19, 1934: Even convalescence, bowels open, no vomiting.—Dr. Evers.

May 21, 1934: Nothing unusual, appetite good, no vomiting.—Dr. Evers.

May 24, 1934: Stitches out, wound clean, uneventful postoperative course.—Dr. Evers.

May 26, 1934: Discharged.—Dr. Evers.

**Condition of discharge:** Recovered, cured.—Dr. Evers. Feb. 8, 1935: I received a letter from the patient in which she writes as follows: "I am very well and am more regular than I have ever been in my life, can eat practically anything, seldom have indigestion and no nausea that I used to have after every meal."

## SUMMARY

A case of incomplete intestinal obstruction due to shortening of ligament of Treitz has been presented because of the rather uncommon nature of the obstruction, and to show the value of close fluoroscopic observation. This case was completely missed in a previous gastro-intestinal series elsewhere.

## Intestinal Tuberculosis

### A Clinical, Roentgenological and Pathological Study of 2086 Patients Affected With Pulmonary Tuberculosis

By

EMIL GRANET, A.B., M.D.\*  
NEW YORK CITY, NEW YORK

ULCERATIVE intestinal tuberculosis is a common disease. That it must be so regarded is shown by the following: 72% of our fatal cases of pulmonary tuberculosis at the Metropolitan Hospital were found at autopsy to have ulcerative enteritis. Furthermore, recent reliable post mortem studies from various localities report ulcerative enteritis as a complication of pulmonary tuberculosis in 65-90%. The total morbidity from pulmonary tuberculosis cannot be estimated accurately. However, vital statistics for New York City in 1933 place the total deaths from pulmonary tuberculosis at 4,500. Based on the statistics quoted, a conservative assumption is that 65% or 3,000 of these suffered with ulcerative enteritis for some time before death. It is apparent from this that ulcerative enteritis is a frequent complication of pulmonary tuberculosis and as such must be seriously regarded as a common clinical entity.

Tuberculous enteritis assumes major importance when present in a patient because of its profound effect on the course of the pulmonary disease. It gravely influences the treatment and prognosis of the patient. We know that a prime factor in treating a tuberculous patient is maintaining or restoring nutrition. The presence of an ulcerative enteritis, interfering as it does with the assimilation of food and furthering the absorption of intestinal toxins, minimizes the possibility of maintaining the nutrition of the patient. Certain it is that without this complication many tuberculous patients now doomed would go on to a successful recovery.

Undoubtedly the presence of extensive intestinal ulcerative lesions at the time of diagnosis accounts for the relatively poor therapeutic results. Brown and Sampson (1), Gram and Flemming-Moller (2), and Klein (3) have had encouraging results only in individual cases. It is reasonable to assume, therefore, that with early diagnosis in the stage of minimal ulceration, the curability of intestinal tuberculosis would be greatly enhanced. With this aim in view this study was instituted. Important factors contributing to

TABLE I

*Relative Incidence of Gastro-Intestinal Symptoms in 1743 Patients Examined Roentgenologically for Tuberculous Enteritis.*

| Class                             | Positive With Enteritis | Negative No Enteritis | Total Patients |
|-----------------------------------|-------------------------|-----------------------|----------------|
| G. I. Symptoms Absent             | 527                     | 824                   | 1351           |

ward a practical method of early diagnosis of tuberculous enteritis have been investigated and evaluated.

Since 1919, when Brown and Sampson published their comprehensive monograph on this subject, many clinical studies have been reported: Smithies *et al.*, (4), Williams (5), Lemon (6). In reviewing these papers one is impressed by the great variety of clinical material, the lack of uniformity of clinical factors and methods of study, and consequently, the wide disparity of statistical data. In this work I have attempted to parallel the method of study used by Brown and Sampson and their associates so far as was practicable with the clinical material and facilities at the Metropolitan Hospital in New York City.

Brown and Sampson report a positive clinical diagnosis of ulcerative enteritis in 1465 (26.4%) of 5542 tuberculous patients from Trudeau and Saranac Lake.

Klein (3) made a clinical diagnosis of tuberculous enteritis in 187 (17%) of 1078 patients with pulmonary tuberculosis in the Veteran's Bureau Hospital at Sunmount.

Williams (4), also at Sunmount, investigated 1088 tuberculous patients. 206 (19%) were considered to have intestinal tuberculosis, distributed according to the type of pulmonary tuberculosis present as follows:

Of 62 minimal cases, 1 had intestinal tuberculosis.

Of 273 moderately advanced cases, 15 (6%) had intestinal tuberculosis.

Of 753 far advanced cases 190 (26%) had intestinal tuberculosis.

Submitted March 7, 1935.

## MATERIAL

2086 patients with pulmonary tuberculosis were personally examined by me for the presence of intestinal tuberculosis. Many of these were re-examined so that the total number of examinations was 2416. These patients were consecutive admissions with the exception that far-advanced toxic, or terminal cases were excluded from this study. Minimal cases as a rule are not admitted to this hospital. Of the 2086 patients, 800 (38%) were found to have definite radiographic evidence of tuberculous enteritis; 1286 (62%) were negative. Patients in whom a doubtful or suspicious diagnosis of enteritis was made and in whom re-examination could not be performed were included in the negative group.

The following factors were considered significant in explaining our comparatively high figures. These patients were largely indigent. For this reason, previous to admission many had had inadequate medical care, many were undernourished and improperly fed and a number were chronic alcoholics. A large number had engaged in manual labor despite the presence of a tuberculous toxemia. Many were Nordics, Orientals and Negroes, racial types known to have little immunity to tuberculosis. Hygienic measures were neglected; many patients persisted in swallowing their sputum. Foci of infection in the teeth, tonsils and prostate were common. Minimal tuberculosis was exceptional; in most of the group the primary lesion was classified as moderately advanced or far advanced.

## METHOD OF STUDY

## 1. Roentgenoscopic.

Patients were examined fluoroscopically 7-8 hours after barium was administered orally following an overnight fast. Films were taken infrequently as this was deemed expensive and unnecessary in the majority of cases. In those patients where doubt existed in the interpretation of findings, re-examination was performed after an interval of at least one week. Persistently doubtful cases were classified as negative. Colon examination by barium enema was performed only exceptionally to help clarify a doubtful diagnosis.

A roentgenographic diagnosis of ulcerative enteritis was considered justified if one or more of the following signs was present:

## A. Cecum and Ascending Colon.

1. Stierlin phenomenon.
2. Spastic filling defect.

3. Filling defect with palpable tumor (granuloma).
4. Persistent irregularity of cecum after re-examination.
  - a. Non-filling.
  - b. Narrowing.
  - c. Persistent irregular spasm of ceco-colic valve.
5. Persistent mottling after re-examination.

## B. Ileum.

1. Segmentation and dilation of ileal loops.
2. Matted, adherent ileal loops.

Presumptive signs such as ileal stasis, hypermotility in the colon, gastric residue and ileo-cecal tenderness when present alone were deemed insufficient evidence on which to base a positive diagnosis.

We did not attempt to interpret lesions in the transverse and descending colon with barium meal administered orally. Several patients when first examined had normal colons. After several weeks or months, re-examination revealed signs of ulcerative enteritis. The contrary was true in other patients in whom the original defect disappeared and an increasingly normal picture ensued. The latter were considered cured or markedly improved.

A discussion of roentgen ray findings and their interpretation is beyond the scope of this paper. The present status of our knowledge of this phase of diagnosis is ably discussed by Brown and Sampson (1), Cherry (6), Gershon-Cohen (7), Gram and Flemming-Moller (2). Extreme conservatism and care are necessary to properly interpret defects in the contour of the ileum and proximal colon. Dr. Gosta Forsell, the eminent radiographer, emphasizes this in his discussion of Gram and Flemming-Moller's paper. He stresses the fact that even in normal individuals "the plastic movements of the mucous membrane can cause the form of the lumen to change from an even tube to the most varied formations. The mucosa may fill it entirely in such a manner that the roentgen picture shows a complete defect or in such a manner that the lumen becomes of varying width and shapes. Such an authoritative statement emphasizes the importance of careful, prolonged fluoroscopic observation and frequent re-examination of doubtful cases to definitely establish the organic origin of a roentgen defect.

The accuracy of diagnosis is difficult to check in most cases. Few patients are operated on and in those that come to autopsy there is often a lapse of months between the time of roentgen examination and the death of the patient. Intestinal lesions may develop rapidly in this terminal stage. Careful roentgenographic diagnosis can be accurate, however, as is shown by the following figures: Brown and Sampson diagnosed tuberculous enteritis clinically in 92 patients who later were operated on or came to post-mortem. In only three were lesions absent in the colon at autopsy. A normal intestine had been diagnosed by X-Ray in 88 patients who were later operated on or autopsied. Only one of them showed ulcerative colitis.

Our results also show a relatively high degree of diagnostic accuracy. Autopsies were performed on 59 of our patients who previously had been examined roentgenographically for the presence of intestinal tuberculosis. In 43 of these, X-Ray diagnosis was confirmed, 29 were positive for enteritis; and in 14, negative X-Ray findings were confirmed by the absence of intestinal lesions. In 6 patients diagnosed roentgenoscopically normal, intestinal ulceration was shown at autopsy. 10 patients, in whom a negative diagnosis

| Positive | 545                | 550                   | 74.0%              | 56.0%                 |
| Negative | 34                 | 180                   | 4.5%               | 18.3%                 |
| Doubtful | 155                | 249                   | 21.3%              | 25.4%                 |

had been made clinically, revealed ulcerative enteritis at autopsy. However, in this last group of 10, the interval between X-Ray examination and autopsy varied from 6 to 28 months. It is probable that intestinal ulcers had developed in the interim, and for this reason the validity of these cases should be questioned. Thus, excluding the 10 cases with the long time interval between examination, X-Ray diagnosis was correct in 43 (88%) of 49 patients in this group.

### 2. Symptoms.

Disease entities associated with toxemia or metabolic disturbances frequently manifest themselves in gastro-intestinal symptoms; this is true also of tuberculosis. It is often difficult, therefore, in a tuberculous individual to differentiate between the gastro-intestinal symptoms caused presumably by the absorption of toxins from the pulmonary lesions, and symptoms engendered directly by the ulcerative enteritis. For this reason, in order to simplify this study, constitutional symptoms such as anorexia, loss of weight, weakness, nervousness, fever; and objective symptoms, such as local tenderness, distention and mass formation were excluded. Only gastro-intestinal symptoms which could be attributed directly to the intestinal pathology were included. Patients were questioned for the presence of symptoms at the time of X-Ray examination. Common complaints such as dyspepsia and constipation were recorded only when the onset of these symptoms approximated the date of onset of pulmonary symptomatology. Vomiting following prolonged seizures of coughing was excluded as a primary gastro-intestinal symptom, as were transient attacks of diarrhea following dietary indiscretions.

We have progressed greatly from the day when intestinal tuberculosis was diagnosed by the onset of intractable diarrhea. All observers agree that symptoms often occur late in tuberculous enteritis. Of 76 patients with tuberculous enteritis who came to post-mortem, Walsh (9) reported that 34% had no gastro-intestinal symptoms during life. I was amazed by the complete absence of gastro-intestinal symptoms in many of our patients who showed roentgen signs of extensive intestinal ulceration. Our figures show that, of 744 tuberculous patients with definite roentgenographic evidence of ulcerative enteritis, only 217 (29%) complained of gastro-intestinal symptoms at the time of examination. 527 (71%) of these had no intestinal symptoms. In 999 tuberculous patients in whom roentgenography showed a relatively normal gastro-intestinal tract 175 (18%) complained of gastro-intestinal symptoms. (Tables I and II).

A number of our positive enteritis cases who were

symptom-free at the time of roentgen examination later developed gastro-intestinal symptoms. In others of this group, symptomatic periods alternated with symptom-free periods. A small number of enteritis patients with symptoms at the time of examination gradually became symptom-free. This change generally coincided with improvement in the original roentgen defect.

It seemed extremely important to us that only 29% of our enteritis cases complained of gastro-intestinal symptoms as compared with 18% of symptomatic cases in the roentgenographically normal group. The etiology of symptoms in this latter group is conjectural at this time and is to be investigated in another study. The comparatively small percentage of symptomatic patients in our positive enteritis group requires elucidation. Many of our patients by their poverty become inured to the rigors of life and consequently are largely hyposensitive to physical discomfort. They tend to minimize the significance of dyspepsia and mild abdominal pain and consequently fail to report these symptoms. The order of frequency of symptoms for patients with intestinal tuberculosis in this group was as follows (Table II): pain, diarrhea, dyspepsia, constipation, constipation alternating with diarrhea, vomiting. In patients with a roentgenographically normal intestine the frequency in order of occurrence was: pain, constipation, dyspepsia, diarrhea, vomiting and constipation alternating with diarrhea. The remarkably small percentage of patients with gastro-intestinal symptoms in our enteritis group emphasizes strikingly the futility of depending on symptomatology to aid in the early diagnosis of intestinal tuberculosis.

### 3. Sputum.

Investigators are largely agreed that tuberculous enteritis occurs as a secondary complication of pulmonary tuberculosis. Extension of the disease to the intestines takes place by direct contamination of the intestinal tract with tubercle bacilli swallowed in the sputum. Hence we expect patients with tuberculous enteritis to have or to have had positive sputums. Furthermore, it follows that a patient with consistently negative sputum reports is unlikely to acquire tuberculous enteritis. This direct relationship of positive sputum to intestinal tuberculosis is important from a diagnostic and prognostic standpoint; consequently it was investigated as part of this study.

The presence or absence of tubercle bacilli in the sputum of patients in this series was noted at the time of intestinal radiography. To simplify essential factors, the method of recording was arbitrarily fixed as follows: Positive—if tubercle bacilli were found at any time during the case history in either sputum or gastric lavage returns. Negative—if tubercle bacilli were consistently absent in five or more concentrated sputum examinations or absent in the gastric lavage returns. Doubtful—if less than five examinations with negative findings were performed up to the time of X-ray examination. Ulmar and Ornstein (10) have frequently demonstrated tubercle bacilli in the gastric lavage returns of patients with consistently negative sputum. Diagnostic lavage of patients with negative sputa has been made a routine practice on this service.

Our investigation confirmed the direct relationship between positive sputum and intestinal tuberculosis. Of 740 patients with intestinal tuberculosis the spu-

tum was negative for tubercle bacilli in only 34 (4.5%). On the other hand of 979 patients with a roentgenographically normal intestinal tract, negative sputum was found in 180 (18.3%). (Table III). Our figures approximate those of Brown and Sampson who report 55 patients (11%) with negative sputum in a group of 519 cases of secondary tuberculous enteritis. From these findings we believe, therefore, that the presence of tubercle bacilli in the sputum favors the onset of a secondary intestinal tuberculosis and further, that a consistently negative sputum precludes this complication. Patients with positive sputum continually re-infect the intestinal mucous membrane by swallowing tubercle-laden sputa. In these patients, therefore, whenever possible, pneumothorax or thoracoplasty is instituted early in an attempt to rid the sputum of tubercle bacilli. Where this desideratum has been attained, healing of existing intestinal lesions without the danger of further infection becomes possible. In a small number of our patients now under observation, clinical and roentgenographic improvement in the enteritis picture followed pulmonary surgical procedures.

#### 4. Sigmoidoscopy.

Peri-anal tuberculosis is frequently seen. Walsh (8) reported 9% in 100 autopsies on patients with pulmonary tuberculosis. Martin (10) found tuberculous ulcers in 5 of 20 patients with far advanced intestinal tuberculosis examined proctoscopically. The rectum was involved in 16% of patients with intestinal tuberculosis examined at post mortem by Goldberg, Sweany and Brown (11).

150 consecutive patients in our series were sigmoidoscoped. Bedridden, toxic patients were excluded. Two patients only in this series showed discrete ulcers in the rectum which had the clinical appearance of tuberculous ulcers. Biopsy was not performed. It seems fair to conclude from this that ulcerative proctitis is a complication which develops late in the disease and sigmoidoscopy, therefore, as an early diagnostic measure is of little value.

Examination of the gastric chemistry, the feces and physical examination, except in tuberculous peritonitis and granuloma of the cecum gave little evidence of practical diagnostic value, and consequently were not considered in this study.

### POST MORTEM STUDIES

#### A. Pulmonary Lesions.

The post mortem study of secondary tuberculous enteritis brings out many facts and relationships which are of use in the clinical diagnosis of this condition. Especially so is the relationship of the pulmonary lesion to the secondary lesion in the intestines. The presence of cavitation in the lungs of a tuberculous patient usually is associated with the presence of positive tubercle bacilli in the sputum of that individual. It has been shown that positive sputum predicates ulcerative enteritis in many cases. We, therefore, expect to find pulmonary cavities in most patients with tuberculous enteritis. This direct relationship has been demonstrated by Brown and Sampson (1) in clinical studies. They showed that in 519 patients with intestinal tuberculosis diagnosed roentgenographically, 329 (63%) had pulmonary cavities. Klein (2) found pulmonary cavities in 214 of 223 cases of secondary intestinal tuberculosis.

In our patients, post mortem examinations confirmed

TABLE IV

*Pulmonary Antra and Tuberculous Enteritis in 266 Autopsied Pulmonary Tuberculosis Patients*

|                | Number               |                    | Percent              |                    |
|----------------|----------------------|--------------------|----------------------|--------------------|
|                | Ulcerative Enteritis | Normal G. I. Tract | Ulcerative Enteritis | Normal G. I. Tract |
| Total          | 192                  | 74                 | 100%                 | 100%               |
| Cavity Present | 185                  | 45                 | 95.4%                | 61.0%              |
| Cavity Absent  | 7                    | 29                 | 3.6%                 | 39.0%              |

the direct relationship between pulmonary cavitation and ulcerative enteritis. (Table IV). Secondary ulcerative enteritis was present in 192 (72%) of 266 patients dead of pulmonary tuberculosis. 185 (95.4%) of the 192 enteritis cases had cavities in the lungs and only 7 (3.6%) had no open lung lesions. The converse of this does not follow. Thus, of the 74 patients in this group who were negative for ulcerative enteritis, 45 had pulmonary cavities and in 29 the lung had no open lesions. The clinical inference to be drawn from these figures is that in tuberculous patients with pulmonary cavity, the gastro-intestinal tract is very likely to become the seat of a secondary ulcerative enteritis. Hence, these patients should be investigated with the possibility of this diagnosis in view.

#### B. Distribution of Intestinal Lesions.

Observers are generally agreed that 80% of intestinal tuberculosis occurs in part at the ileo-cecal region. The explanation for this distribution lies in the anatomical and physiological factors which favor the local implantation of the tubercle bacillus. Among these may be mentioned concentration of lymphatic tissue (Peyer's patches and solitary follicles) in the ileo-cecal region, the presence here of fluid intestinal chyme, stasis of the intestinal contents in the cecum and at the ileo-cecal valve, the mechanical irritation of the stream of chyme against the edges of the ileo-cecal valve and the point in the cecum on which this stream impinges.

The localization of the intestinal lesions in the ileo-cecal region has an important clinical significance in roentgenographic diagnosis. As stated above, most positive diagnoses of tuberculous enteritis follow the roentgenoscopic finding of defects in contour of the barium filled cecum and ascending colon.

In our series of 192 patients with tuberculous enteritis, the cecal region was the seat of pathology, wholly or in part, in 167 (86%). The distribution of lesions in this group was tabulated according to the anatomical location in individual cases. (Table V). Localization in the ileo-cecal region was most frequent (53), involvement of the entire tract was next (38), cecum alone was third (33). From a study of the distribution of the lesions we can infer that about 90% of the intestinal lesions occur in the terminal ileum, cecum and ascending colon. In this portion of the gastro-intestinal tract, ulcerative lesions usually manifest themselves as spastic defects in contour and so are recognizable on roentgenographic examination. We have no reliable method of recognizing early lesions in the jejunum and proximal ileum, but we find that lesions in this region occur in only 14% of our

TABLE V

*Distribution of Lesions in 192 Cases of Tuberculous Enteritis*

| Location                                   | Number | Percent |
|--------------------------------------------|--------|---------|
| Total                                      | 192    | 100%    |
| Ileo-Cecal                                 | 53     | 31.0%   |
| Cecum Only                                 | 33     | 17.0%   |
| Entire Small and Large Intestine           | 38     | 19.0%   |
| Ileum, Cecum and Ascending Colon           | 27     | 14.0%   |
| Ileum Only                                 | 19     | 10.0%   |
| Cecum, Ascending Colon                     | 9      | 4.5%    |
| Jejunum Only                               | 3      | 1.7%    |
| Jejunum, Ileum, Cecum                      | 4      | 2.0%    |
| Jejunum, Cecum                             | 1      | 0.5%    |
| Jejunum, Ileum                             | 3      | 1.7%    |
| Ascending, Transverse and Descending Colon | 1      | 0.5%    |
| Sigmoid Only                               | 1      | 0.5%    |

autopsied cases. During life it is likely that the number of cases with jejunal ulcerations must be even smaller and, therefore, the diagnostic error here encountered can be disregarded with impunity.

#### DIFFERENTIAL DIAGNOSIS

Pathological conditions, non-tuberculous in origin, occurring in the terminal ileum or colon of patients with pulmonary tuberculosis are likely to be inaccurately diagnosed as tuberculous. This is so because of the morphological similarity of roentgen defects in this region. Suffice it, in this report, merely to mention several important intestinal lesions that require differentiation.

*Terminal ileitis*, a non-specific inflammatory lesion involving the terminal ileum, recently described by Crohn *et al.*, (12) may simulate a spastic narrowed tuberculous *ileitis*. Malignant neoplasms of the cecum cannot be differentiated roentgenographically from tuberculous granuloma of the cecum. *Inflammatory diverticulitis* of the colon occurring in the cecum and ascending colon may stimulate tuberculous enteritis. In these conditions only exploratory laparotomy can establish the correct diagnosis and should always be performed early in doubtful cases.

*Chronic non-specific ulcerative colitis and amebic or bacillary dysentery* when localized, can closely resemble the roentgen picture of tuberculous enteritis. In these conditions diagnosis depends on the clinical course of the case, sigmoidoscopy, the bacteriology and serology of the stool cultures, stool examinations for ameba, and the successful response to specific therapy when this is feasible.

On our service we have made it a practical rule that, in tuberculosis patients, intestinal lesions showing persistent roentgen defects are considered tuberculous until proved otherwise, especially when the sputum is positive for tubercle bacilli.

#### THERAPY

The successful treatment of intestinal tuberculosis depends primarily on one key factor, namely, inactivation of the source of infection in the lungs. Absorption of toxins from active lung lesions by their noxious systemic effect prevents healing of intestinal lesions. Furthermore, the intestinal mucosa is constantly being re-infected with tubercle bacilli swallowed in the sputum expectorated from active parenchymal foci. While these factors are present it is useless to expect permanent cure in the secondary intestinal lesions. As stated above, the prime emphasis in therapy must be directed toward attaining a negative sputum and a decrease in toxic absorption.

The treatment of the intestinal lesions must be undertaken simultaneously and the measures used are twofold, *general and specific*. The general measures undertake to improve nutrition, help tissue repair, and strengthen immunity. These include actino-therapy, a high caloric, low roughage diet, the administration of vitamins C and D, iron for secondary anemia, calcium salts, and where indicated, insulin to stimulate appetite.

Specific local treatment is directed primarily toward fostering peristaltic rest in the involved segments of the intestine. Treatment depends on individual symptomatology and must be changed frequently to suit the clinical course of the case. A smooth, low residue, high caloric diet, similar to a maintenance peptic ulcer diet, to which is added tomato juice and cod liver oil as advocated by McConkey, is our standard dietary. Such a diet reduces peristaltic action to a minimum and provides an excess of vitamins C and D, shown to be of value in the metabolizing of calcium and the stimulation of mucosal healing. Abdominal pain is controlled by heat or adequate sedatives. Constipation is helped by small amounts of mineral oil or by gently administered warm saline enemas. Diarrhea is controlled by administration of barium sulphate or kaolin in half ounce doses administered frequently and, if necessary, tincture opii deodorata in effective doses. Dyspeptic symptoms usually improve on sedation, carminatives or alkalies.

Surgical therapy has definite indications in the treatment of certain types of intestinal tuberculosis. Unfortunately it is often too long delayed. Granulomatous lesions should be resected. Acute tuberculous appendicitis is frequently seen and here operative delay may be costly. Perforation of tuberculous ulcers with resulting peritonitis is a condition always to be expected, and here neglect of immediate operative repair is fatal. Partial colectomy for early, localized, ulcerative tuberculosis has been advocated but we have not felt it an advisable procedure in our cases. Our experience has been that, with elimination of re-infection and careful individualization of symptomatic medical treatment as described, ulcerative intestinal lesions tend to improve clinically and roentgenographically. We have never observed consistent improvement in the intestinal lesions of patients in whose lungs the disease process increased in activity.

## SUMMARY AND CONCLUSION

Tuberculous enteritis is a common disease and is present in most patients with advanced pulmonary tuberculosis. 2086 tuberculous patients were studied clinically and pathologically in an attempt to delimit criteria which would facilitate early diagnosis and better therapeutic results. This study was limited to moderately advanced and advanced non-toxic patients with pulmonary tuberculosis.

Roentgenoscopy of the gastro-intestinal tract revealed lesions in 37% of our patients. Postmortem check-up showed a relatively high degree of accuracy for this method of diagnosis. A history of gastro-intestinal symptoms was found to be unreliable as a

diagnostic aid inasmuch as symptoms were absent in the majority of positive enteritis cases. Furthermore, the percentage of patients complaining of gastro-intestinal symptoms was only slightly greater in the positive enteritis group than in the negative patients. A study of the sputum showed tubercle bacilli in practically all positive enteritis cases. Similarly almost all fatal cases with enteritis had pulmonary cavities when examined at autopsy. Sigmoidoscopy revealed rectal involvement only in 2 of 150 patients examined.

Differential diagnosis was considered and principles of therapy were outlined.

Therapy was described briefly and emphasis was placed on treatment of the primary focus of infection as well as of the intestinal lesions.

## Stomach Lavage Microscopy as an Aid in the Diagnosis of Biliary Tract Disease\*

By

HENRY A. RAFSKY, M.D., F.A.C.P.<sup>†</sup>  
NEW YORK CITY, NEW YORK

(1)

IN a previous paper, I reported the fact that crystalline elements were observed in the stomach lavage of patients with cholelithiasis. In an effort to approximate the diagnostic significance of this finding, this subject was further investigated in a series of patients with and without biliary tract disease. In this study microphotographs of the crystalline elements seen in the stomach lavage, before operation, were compared with microphotographs of the crystals, found in the bile and stones removed from the gall bladder and bile ducts at the time of operation.

### MATERIAL

In this series 91 patients were studied and were grouped as follows:

1. 53 patients (58.2%) in whom biliary tract disease was diagnosed and who subsequently came to operation.
2. 18 patients (19.7%) in whom biliary tract disease was diagnosed but who did not come to operation.

3. 20 patients (22.1%) who comprised the control group. In these patients, there was no history or clinical evidence of biliary disease.

### METHOD OF STUDY

The method of procedure was as follows: A gastric lavage with warm tap water was performed in the morning, while the patient was in a fasting state. The lavage water was then collected and examined microscopically for crystalline elements. When crystals were present, they were usually found in the grayish or brownish red particles imbedded in the mucus or they were seen in the lavage water independently of the mucus. In the patients in groups 1 and 2, an attempt was made to do the gastric lavage in the morning, following an attack of biliary colic or gastric disturbances of sufficient severity to disturb the patient's sleep. It was found that when the lavage was obtained under these circumstances, the crystalline elements were present in large amounts.

In Group 1, there were fifty-three patients in whom biliary tract disease had been diagnosed and who subsequently came to operation. Crystalline elements were found in appreciable amounts in the stomach lavage, before operation, in forty-six of these patients (86.8%). In the remaining seven patients (13.2%) few or no crystals were seen in the gastric lavage. A study of the crystal morphology as observed in the

Fig. 1

stomach lavage, before operation, of the patients in this group, revealed the following: (Table 1.)

Numerous cholesterol crystals separately or together with carbonate crystals in seven patients (13.2%); a large amount of calcium bilirubinate pigment in five patients (9.4%); a shower of cholesterol crystals (with or without carbonate crystals) together with a moderate or large amount of calcium bilirubinate pigment in thirty-four patients (64.2%); and few or no crystalline elements in seven patients (13.2%). The operative findings of the patients in Group 1, were as follows: Calculous cholecystitis (including choledocholithiasis) in forty-one patients (77.3%); non-calculous cholecystitis in nine patients (16.9%); and no macroscopic evidence of biliary disease in three patients (5.8%).

Two of the patients in Group 1, had been subjected to cholecystectomy for gall stones, one, eleven years ago, and the other, nine years ago. An abundant amount of calcium bilirubinate pigment was found in the stomach lavage in both of these patients when they were examined recently. When they were operated again, stones were found in the common bile duct.

In Group 2, there were eighteen patients in whom biliary tract disease had been diagnosed, but who did not come to operation. Cholesterol and carbonate crystals and calcium bilirubinate pigment separately or collectively, were present in appreciable amounts in the stomach lavage in fifteen of these patients (83.3%). Few or no crystalline elements were found in three patients (16.7%). Cholecystography on the patients in this group revealed the following: Definite evidence of calculi or a persistent "no shadow" cholecystogram in five patients (27.8%); a gall bladder shadow fainter than normal in six patients (33.3%); roentgenographic evidence of a papilloma of the gall bladder in two patients (11.1%) and a normal func-

Fig. 1. Patient R. S.—Cholesterol and carbonate crystals together with calcium bilirubinate pigment (preoperative specimen of stomach lavage).

tioning gall bladder shadow in five patients (27.8%).

Group 3, which comprised the control group, consisted of twenty patients in whom there was no history or clinical evidence of biliary tract disease. Stomach lavage microscopy revealed the following: No crystalline elements in eleven patients (55.0%); few biliary crystals in seven patients (35.0%); numerous cholesterol crystals and a slight amount of calcium bilirubinate pigment in two patients (10.0%). One of the latter, when informed of the findings from the stomach lavage, recalled that he had a tape worm nine years ago. The other patient had diabetes.

### COMMENT

With a view of approximating the diagnostic significance of the presence of crystalline elements in the stomach lavage, a group of patients with and without biliary tract disease was studied. Cholesterol and carbonate crystals, as well as calcium bilirubinate pigment, separately or collectively, were found in most of the patients with proved calculous or non-calculous cholecystitis. In these patients with biliary tract disease, who came to operation, the crystalline elements observed in the preoperative specimen of stomach lavage were found to be similar to the crystals seen in stones and bile removed from the gall bladder, at operation. The crystals were found more consistently and in larger quantities when the lavage was performed in the morning following an attack of biliary colic.

The presence of the crystals in the stomach lavage is due to the regurgitation of the bile into the stomach. In about one-half of the patients the contents from the gastric lavage was deeply bile tinged.

Crystalline elements were found in the stomach lavage in patients with calculous as well as non-calculous cholecystitis. Of the patients in whom microscopic examination of the stomach lavage revealed many cholesterol crystals together with abundant calcium

Fig. 4. Patient A. B.—Cholesterol crystals together with calcium bilirubinate pigment (scraping of stone).

bilirubinate pigment, cholelithiasis (including cholelithiasis) was found in 97.1 per cent of the patients.

Crystalline elements, to have diagnostic significance, should be present in the stomach lavage in appreciable numbers. Few or no crystals in the stomach lavage,

nostic value of the microscopic examination of the stomach lavage in biliary tract disease:

#### CASE REPORTS

Case 1.—R. S., age 57, female, white, married, com-

Fig. 5. Patient J. K.—Cholesterol and carbonate crystals (preoperative specimen of stomach lavage).

Fig. 6. Patient J. K.—Cholesterol and carbonate crystals, bile stained mucus and slight amount of calcium bilirubinate pigment. (Bile from gall bladder).

however do not rule out biliary tract disease, especially if the examination is made when the patient is symptom free or if very large calculi are present in the gall bladder. More than one lavage may be necessary before the crystals are recovered.

The following case reports will illustrate the diag-

plained of periodic attacks of abdominal pain for five years. The pain was localized in the right upper quadrant, radiating to the right shoulder. Physical examination revealed tenderness over the gall bladder region. Microscopic examination of the stomach lavage showed the presence of cholesterol and carbonate crystals and calcium bilirubinate pigment in the same particle (Figure

1). Cholecystography indicated the presence of numerous biliary calculi. The patient was operated upon and about three hundred stones were removed from the gall bladder. The scrapings of one of these stones showed the presence of cholesterol and carbonate crystals and calcium bilirubinate pigment similar to those in the stomach lavage before operation (Figure 2.)

*Case 2.*—A. B., age 50, female, white, married, gave a history of recurrent attacks of biliary colic for seven years. The pain was localized over the gall bladder region and it radiated to the region of the spine. There was tenderness over the epigastrium and gall bladder regions. Microscopic examination of the stomach lavage revealed cholesterol crystals together with calcium bilirubinate pigment (Figure 3). Cholecystography showed a gall bladder shadow faintly outlined, but, no stones were discernable. The patient was operated and eleven stones were found in the gall bladder. The scrapings of one of these stones showed the presence of cholesterol crystals and calcium bilirubinate pigment (Figure 4).

*Case 3.*—J. K., white, male, married, gave a history of having had severe attacks of pain in the abdomen occurring about once monthly for the past two years. The pain was located in the epigastrium and radiated to the right shoulder and then down the right inguinal region. Physical examination revealed tenderness over the right upper quadrant. Microscopic examination of the stomach lavage showed the presence of cholesterol and carbonate crystals (Figure 5). Roentgenographic examination of the kidneys did not reveal any abnormality. A roentgenographic examination of the gastro-intestinal tract showed a pylorospasm with no definite evidence of ulceration. Cholecystography indicated a normal functioning gall bladder shadow. An exploratory laparotomy was performed on the patient and the following was found: The gall bladder was covered with adhesions especially on the right lower surface. Part of the adhesions were attached to the anterior wall of the second portion of the duodenum. The stomach and duodenum did not show any evidence of ulceration or malignancy. The gall bladder was removed. Microscopic examination of the bile from the gall bladder showed the presence of cholesterol and carbonate crystals (Figure 6). The report of the pathological examination of the gall bladder was "Chronic Catarrhal Cholecystitis".

# CONCLUSION

1. In a group of patients with proved calculous and

non-calculous cholecystitis the microscopic examination of the stomach lavage revealed the presence of biliary crystals in appreciable amounts in a large percentage of the patients.

## A Clinical Interpretation of Duodenal Diverticulum\*

By

HERMAN H. RIECKER, M.D.†  
ANN ARBOR, MICHIGAN

**R**EGARDED as an anatomical curiosity until 1913, when the first case was diagnosed by Roentgen ray, the duodenal diverticulum, now not an uncommon lesion, still lacks uniformity in the interpretation of its etiology and significance in gastroenterology. Its classification has been most studiously attempted by Odgers (1), who, however, followed the pre-roentgen conception of a primary type (false, congenital, *hernias*

*tunicaries*), occurring in the second or third part of the duodenum, and the secondary type (true, acquired) appearing only in the first part of the duodenum. Odgers' views, reflecting those of the pathologist, are that the "primary" type probably is due to congenital areas of local, decreased resistance to pressure, and he believes, with Nagel (2), that it is not associated etiologically with ulcer.

Bensaude (3) suggested five predominant groups of symptoms referable to the presence of diverticula, but these are confusing and difficult to apply in attempting

\*From the Department of Internal Medicine, University of Michigan Medical School.

†Assistant Professor of Internal Medicine.  
Submitted April 3, 1935.

Fig. 1

a clinical diagnosis. Since gastro-intestinal symptoms almost always are caused by an abnormal motility there is some question as to whether duodenal pouching is the cause or result of motility changes in this organ. It is impossible consistently to diagnose a diverticulum from the history alone and even to hazard a guess as to its presence is not wise.

It was with the problem of defining a possible clinical picture and arriving at a clinical interpretation of the meaning of the diverticulum as revealed by X-ray that the 35 cases in the files of the University of Michigan Hospital were reviewed; many of these cases personally were examined. The following results came from this study:

Twenty-two (22) cases had the usual history of duodenal ulcer and were so diagnosed provisionally by the examining physician.

Thirteen (13) of these were cases of peptic ulcer associated with diverticulum. In the remainder no lesion of the stomach or duodenum was demonstrated other than diverticulum. Of these 13, the diverticulum was localized by X-ray in the first portion of the duodenum in three, in the second portion in five, and in the third portion in five.

This survey indicated in a surprising way that the most common history and the most consistent associated lesion was peptic ulcer.

A review of the literature since 1914 was made in an effort to confirm or deny three current statements that diverticulum is usually of congenital origin, has no definite clinical history, is a purely incidental finding, and is not associated commonly with peptic ulcer or other disease of the upper abdomen. In many clinical case-reports the data presented was insufficient to

Fig. 1. Showing ulcer and large diverticulum in third portion. Female *aet* 54.

be of value for this purpose. However, 40 cases were found in which peptic ulcer was associated with diverticulum; the location of the latter, where stated, is detailed in Table I.

My own cases, as well as those found in the literature, indicated definitely that duodenal ulcer not uncommonly preceded the appearance of the diverticulum. There was no particular site for the location of such diverticula, as would be postulated necessarily in the classification of Odgers' and others who believe that only the secondary type is associated with this lesion.

Clairmont (4) gave an excellent discussion of this factor, recognizing cases in which ulcer preceded diverticulum. Denis (5) wrote that, clinically, the diverticulum often gives the symptoms commonly attributed to ulcer. Spriggs and Marxer (6) believed that, as a rule, the diverticula are not congenital and not associated with ulcer, although they report 47 per cent of 38 cases having epigastric distress after meals. In 30 cases reported by Cole and Dudley (7) eleven had pylorospasm and three showed gastric ulcer. In 100 cases characterized usually by epigastric distress and pylorospasm, and diagnosed as unstable or irritable duodenum, Friedenwald (8) found five instances of duodenal pouching. Gibbon (9) reported 20 cases, in nine of which epigastric symptoms occurred one to four hours after meals. Edwards (10) classified the symptomatology of 27 cases into (1) the flatulent dyspepsia of a filled pouch, and (2) epigastric pains after food which he interpreted as diverticulitis. Spriggs (11) in reporting 10 cases says that the diverticulum usually does not cause symptoms although in nine of these there was other abdominal disease. Sennett (12) reported four cases, one of which was associated with ulcer and the other presenting epigastric symptoms

Fig. 2

Fig. 2. Ulcer of duodenum. Diverticulum not visible as such but showing what appears to be a pouch in first portion of duodenum.

similar to those of ulcer. Zanetti (13), in discussing ulcer and ulcerated diverticulum, says that in his experience there is no difference between the symptom of ulcer of the bulb and of lesions further along in the duodenum, suggesting a belief that a diverticulitis can cause the symptoms of ulcer. Smithies, in discussing a paper by Case in 1920 (14), said that the symptomatology (of diverticulum alone) does not resemble that of ulcer. Kellogg (15), in discussing the symptoms, says that the pain frequently is intermittent, usually related to the taking of food and occurring from one to three hours after eating.

The usual duodenal ulcer history is closely simulated by reflex pylorospasm, by duodenitis, and by the irritable duodenum described by Friedenwald, and a diverticulum, of course, can be found under such circumstances. It is doubtful whether a diverticulum ever is primary or congenital, although a congenital predisposition for such lesion easily can be postulated. In one of our cases in whom an operation was preferred healed ulcer was found in a diverticulum of the first portion, but as a rule the pouch in this location is opposite the ulcer.

In 1893, Dr. Charlewood Turner was quoted by Perry and Shaw (16) as follows: "The pouching of the wall of the duodenum is to be attributed to a distension from irregular and spastic contraction due to irritation of the ulcerated surfaces." This gem of clinical reasoning appears to be the soundest explanation of origin of diverticula because the pouching occurs at the site of entering veins along the attachment of the duodenum usually in older subjects, and very rarely in children.

That a reflex spasm of the duodenum may be postulated to explain those cases in which an ulcer could not have been present is shown by the frequency of disease in other parts of the gastro-intestinal system in reported cases. In one of our cases there was a

cancer of the colon and in several, gallstones. In several case reports gallstones were found either by X-ray or at operation. A local spasm of the pyloric area usually accompanies active ulcer and the large majority of diverticula are of the false or herniated type, thus offering a sound functional basis for their formation. Lensmayer and Baldwin's (17) 60 post mortem examinations showed only four true types, all in the first part of the duodenum.

In two of our cases the diverticulum from a series of X-ray studies appeared to have developed several years after the ulcer had been demonstrated. Fig. 1 illustrates such a case in a woman 54 years of age in whom ulcer had been present periodically for 30 years. This diverticulum was not found in studies five years previously. It is obvious from the cases reported that there is neither a relation between the symptoms and the site of the diverticulum, nor between the presence of an ulcer and the position of the diverticulum. The evidence from a clinical standpoint does not permit a classification such as that of Odgers'. A queer event occurred in one of our cases in which a man of 44 years complained of symptoms strongly suggestive of ulcer over a period of 15 years, his father having died of cancer of the stomach. The X-ray diagnosis was duodenal diverticulum. A second X-ray study 10 years later failed to demonstrate the diverticulum. This instance, together with the fact that surgeons complain commonly of not being able to find a roentgen-demonstrated diverticulum (but sometimes an ulcer), brings into question the actual incidence not only of the deformity but associated ulcer as well, since the latter heals and reappears periodically in a lifetime. Because of the difficulty in demonstrating a diverticulum in the third portion of the duodenum, and because of the herniated character of its structure, often into the body of the pancreas, as well as a dependence on the fluoroscopic examination for the demonstration of a lesion which may have a very narrow neck, and depend for its filling upon the activity of the duodenum, the actual incidence of pouches is difficult to determine. So many have been reported from autopsy studies, with accurate location of the pouch that, for lack of definite evidence to the contrary, we may conclude that once formed the pouches are permanent. An X-ray demonstration of diverticulum without ulcer does not vitiate the probability of their common association unless the past history, associated psychic pattern, and body type also speak against the diagnosis of ulcer.

From the data obtained in reported cases and my own observations, it may be said that a typical clinical picture of duodenal ulcer occurs in about two-thirds of the cases of diverticulum. It is not unlikely that in these cases the same mechanism is at work as that producing the symptoms of duodenal ulcer, namely, a motor disturbance at the pyloric region, as described by Turner. On the same basis the evidence suggests rather strongly that the "primary" or false diverticulum is commonly produced by a motor disfunction in the duodenum and is usually seen in long standing cases of peptic ulcer. The secondary, or true type, of course, always is associated with ulcer. Whether a diverticulum can be said to be a complication of ulcer is not easily decided, since ulcers have been seen in di-

Fig. 3

Fig. 3. Same patient as in Fig. 2. This exposure shows diverticulum with stalk, arising from third portion of duodenum.

verticula, a diverticulitis is possible, emptying of the pouch may be delayed and a vicious circle of irritability established. In a few instances certainly the diverticulum acts prominently as a complicating factor in producing epigastric discomfort.

When the symptoms in any given case are those of duodenal ulcer, and a diverticulum is demonstrated by X-ray, a more careful survey of the life of the patient often will lead to the diagnosis of ulcer; however, if diverticulum is demonstrated in a case not suspected of being ulcer, it is more than likely that the diverticulum is not causing symptoms and a further study for reflex or functional causes of the symptoms must be made. Such lesions may be any of a large number responsible for pylorospasm including other diseases of the duodenum. These observations naturally follow from the original statement of Turner, and if

acted upon, a clearer understanding of the basis of symptoms will follow.

### CONCLUSION

(1) Clinical evidence suggests that diverticula of the duodenum are associated with reflex changes in the motility of that organ and are secondary to ulcer as the commonest lesion in this region.

(2) The most usual symptoms and signs accompanying the Roentgen demonstration of duodenal diverticulum, regardless of its site, are similar to those of duodenal ulcer, and frequently are accompanied by pylorospasm. There is no evidence that the diverticulum itself causes these symptoms.

(3) In all cases it is best to consider the diverticulum as secondary to pylorospasm and to search carefully for disease or reflex disturbances before treating the lesion as a primary one.

## SECTION II—*Experimental Physiology*

### The Mechanism of the Delay in Gastric Emptying Time Caused by Anoxemia\*

By

GEORGE CRISLER, Ph.D., M.D., E. J. VAN LIERE, Ph.D., M.D.

and

I. A. WILES, M.S.

MORGANTOWN, WEST VIRGINIA

IN previous communications (1), (2), we have reported that anoxemia causes a delay in the evacuation of the stomach. Although marked individual variations in the response of different animals to anoxemia were observed, most animals manifested some delay at 560 mm. of pressure and only one out of 29 dogs failed to show delay at 450 mm. of pressure. The findings naturally raised the question of the mechanism of the delay.

It seemed logical to start the investigation for answering this question by determining the effect of anoxemia on the pyloric sphincter. Also, since the vagi are predominantly concerned with the motor mechanism of the sphincter we directed our attention to these nerves. Further, vagospasm from anoxemia has been demonstrated by Eyster and Meek (3), Greene and Gilbert (4), Van Liere and Crisler (5) and others. All of this work was focused on the relation of the vagus to the heart under anoxemia, though Greene (6), suggested that the effect might be expected in its relation to the gut. We, therefore, originally suggested that anoxemia causes a vagospasm which leads to a pylorospasm which in turn is the actual cause of the slowed emptying. In some "acute" experiments performed in the meantime (7), we found that anoxemia, produced by 10 per cent oxygen or less in the inspired air of anesthetized dogs, invariably caused a fall in tone and a decrease in the amplitude of contractions of the filled stomach. The data in this paper show that the effect of anoxemia on the emptying of the stomach may be divided, depending upon the severity of the anoxemia, into those attributable to the pylorospasm, as we suggested, and into those attributable to a decreased motility of the stomach.

#### METHOD

Normal and control anoxic gastric emptying times were established in 14 dogs. The diet and experimental procedure were those reported in our former paper (2). The degrees of anoxemia used were 760, 560, 450 and 360 mm. of pressure corresponding respectively with 20.96, 15.45, 12.75 and 9.94 per cent oxygen and to 0; 8,200; 13,750 and 19,265 feet in altitude. The animals were then subjected

to various operative and experimental conditions and corresponding emptying times were determined. Throughout this paper we have called the emptying time at 760 mm. before operation, "the normal emptying time", and after the various operations, "the postoperative normal". Some animals were used for more than one procedure so that more than fourteen individual series of experiments were performed. In nine animals the pyloric sphincter effectively was obliterated, as checked at autopsy, by pyloroplasty (Rammstedt's operation). In two of four dogs the pyloric outlet was supplemented by a posterior gastro-enterostomy and in the other two it was excluded, the pylorus being ligated at the time of the performance of the gastro-enterostomy. In four animals 1/100 gr. of atropine was given just before each test in the experimental series at various degrees of anoxemia. In one animal the vagus fibers to the pylorus were sectioned by making a circular incision around the stomach down to the mucosa about 1 cm. proximal to the pyloric orifice, the muscular layers being held together by four anchor stitches which served to prevent undue retraction of the cut structures. While this procedure probably does not deprive the more distal portion of the pylorus, including the sphincter, of all of its parasympathetic innervation, it does interrupt most of the fibers and the results were clear enough that we may assume we were dealing with complete parasympathetic denervation.

#### RESULTS

The animals in the present series make the individual variations in the normal emptying times between different animals more apparent than ever, so that in most of the tables we have expressed the effect in terms of 100 per cent for the normal emptying time and for the postoperative normal. This serves to make the variations of different animals apparent only under experimental anoxic conditions while the variations in the normal emptying times before and after experimental operative procedures are concealed. The numbers in the tables represent the average of a number of tests in each case. Because we determined the emptying times to a + or -15 minutes only, the accuracy of our tables is within about 8 per cent; hence, a change of less than this amount is insignificant unless all values vary in the same direction.

*Effects of operative procedures per se.* In Fig. 1 the results of a typical animal in each group are shown in hours. It will be noted that after the various opera-

postoperative convalescence. These results will be dealt with at length in another paper.

**Pyloroplasty.** After pyloroplasty and under anoxemia the stomach did not empty more slowly than the postoperative normal until a stage of anoxemia well below that causing slower emptying before operation was reached. In fact, after the operation at 560 mm. the stomach emptied faster than the postoperative normal, in spite of the fact that it emptied slower than the normal at 560 mm. before operation. At 450 mm. the stomach emptied essentially in the postoperative normal time, there being both increases and decreases with an average of 106 per cent, which is not significant when compared with the slower emptying that resulted in every case before operation. At 360 mm. the stomach emptied slower than the respective normal emptying time both before and after operation although the delay was much more marked before operation. These results are summarized in Table 1A.

**Gastro-enterostomy.** In two animals tested at 560 mm. the stomachs emptied slower than normal before the gastro-enterostomy was performed and suggested faster than the postoperative normal afterwards. At 450 mm. the stomachs of all the animals emptied slower than the normal before operation while in only one case did they empty slower than the postoperative normal after operation. Thus 450 mm. does not as a rule cause slower emptying after gastro-enterostomy. In the two dogs tested at 360 mm. the stomach still did not empty slower than the postoperative normal in one,

while in the other it did empty more slowly after operation but the retardation was not nearly of the same magnitude as before operation. These results are summarized in Table 1B.

**Atropine.** Atropine caused the stomachs to empty slower in every case. The normal emptying time was delayed 26 to 47 per cent and the delay at 450 mm. was approximately of the same magnitude. The delay in the normal emptying time with atropine could not, however, be used to foretell the magnitude of the delay under anoxemia with atropine. (See Table 1C).

**Parasympathetic denervation.** In the one animal with an almost completely parasympathetically denervated pyloric sphincter, results very similar to those for pyloroplasty and gastro-enterostomy were obtained. The animal was one of the rather rare ones whose stomach emptied faster than normally at 560 mm. before operation, but after denervation it emptied still faster. At 450 mm. the stomach emptied distinctly slower than normal before operation, while it emptied in the postoperative normal time after operation. At 360 mm. more marked slowing occurred before than after operation. After completion of the data on this animal, as a check on the efficacy of the denervation, the peripheral end of the vagus was stimulated under ether. The typical pylorospasm did not occur and at autopsy scar tissue forming a bridge across the suture line was found, but time had not been allowed for any functional vagus regeneration. These results are summarized in Table 1D.

## DISCUSSION

We now have a series of 29 dogs all of whose stomachs emptied more slowly during anoxemia, confirming our previous report on 6 animals. We never have had a dog whose stomach failed to show the delay at some stage of anoxemia. The threshold for the delay in most animals lies around a pressure of 560 mm. (15 per cent oxygen), though three animals showed faster emptying at this grade of anoxemia. If vago-spasm is the mechanism involved in the delay, one might reason that the motor effect of the vagus on the stomach in these exceptional cases is prepotent over its motor effect on the pylorus.

The removal of the pylorus by operative section left the emptying time of the stomach dependent upon its own motility, there being no impediment to the outgoing food. In this instance reducing the pressure to 450 mm. (12.75 per cent oxygen) usually did not delay evacuation. When the pylorus was replaced or supplemented by gastro-enterostomy the same effects obtained. These results indicate that in the less severe grades of anoxemia the stomach empties slower because of pylorospasm, for it empties slower before pyloroplasty and gastro-enterostomy but in the postoperative normal time afterwards. It should be re-emphasized that the threshold values for anoxemia vary with different animals so that it is possible for one animal to give the same sort of response at 450 mm. pressure as another would at 360. As a rule, however, we consider the threshold before operation to be 560 mm. and after operation 450 mm. That is, if the pylorus can be thrown into spasm, the stomach will empty slower at pressures between 560 and 450 mm. because of the spasm. When pressures below 450 mm. are used then the stomach empties slower, partially or entirely, depending upon whether the pylorus is functional or not, because of decreased stomach motility.

Atropine cannot be used to test the presence of vagospastic pylorospasm for the motor fibers to the stomach as well as those to the pylorus are paralyzed. Such a paralysis of the motor fibers to the stomach causes it to empty slower as has been shown by Fetter, Barron and Carlson (8), and other authors and most recently redemonstrated by Meek and Herron (9).

It seemed to us that the only way to denervate the pylorus parasympathetically without disturbing the vagus innervation to the stomach was to cut the fibers intramurally in the manner described above. Atropine and vagus nerve section could not be relied upon. The animal in which this was done (Table 1D, Fig. 1D.) acted in every way similar to the animals with pyloroplasty and gastro-enterostomy. As already pointed out there may still be a remnant of parasympathetic innervation to such a pylorus, but it is of no consequence. Thus, we have concluded that our hypothesis is essentially correct, namely that anoxic pylorospasm is on a vagospastic basis and accounts for the delayed evacuation resulting from reduced pressures down to a certain range (450 mm. in most animals). This conclusion is further supported by the fact that after the retarding influence of a vagospastic pylorus on gastric evacuation was removed, regardless of how it was done, the stomachs of all the animals emptied faster than the postoperative normal at a pressure of 560 mm. and some of them even at a pressure of 450 mm. This we interpret as meaning that when the vagus stimulation is prevented from

at this grade). These findings indicate that the delay at 360 mm. in an unoperated animal has a complex genesis, only part of it being explained by the vagospastic pylorospasm. Other additive causes may be the direct effect of anoxemia on the smooth musculature of the stomach, a stimulation of the sympathetics with a tendency to depress stomach motility, a liberation of adrenalin tending to inhibit the stomach through stimulation of the sympathetics, or a combination of any or all of these. One is also led to speculate as to the part *sympathin* might play. The invariable fall in tone and decrease in amplitude of contractions of the filled stomach, which we reported to result from anoxemia (7), were obtained in anesthetized dogs with 10 per cent oxygen or less. These results harmonize with our present results on unanesthetized animals, because 10 per cent oxygen corresponds to about 360 mm. of pressure, and indicate that decreased motility of the stomach is the additional cause of its slower emptying when subjected to severe grades of anoxemia.

In another paper (Van Liere, Crisler and Wiles, in press) we have reported the effects of anoxemia on the pylorus of anesthetized dogs. In such experiments we were unable to predict what the effect might be, because, even in the same animal at different times, we obtained opposite results. Sometimes a tendency towards a pylorospasm was abolished by double vagotomy, and sometimes it persisted afterwards. We concluded that the diversity of results was to be explain-

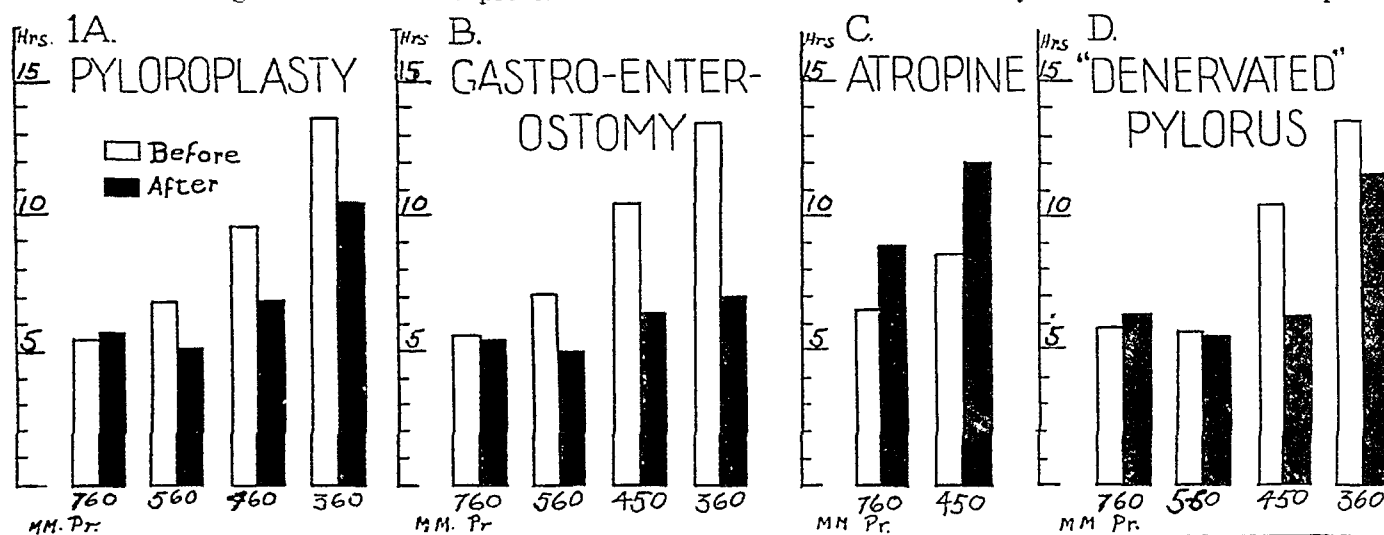

Fig. 1. A typical dog in each case showing the influence of A. pyloroplasty, B. gastro-enterostomy, C. atropine and D. parasympathetic denervation of the pylorus on the emptying times of the stomach in hours under various degrees of anoxemia. Note that the postoperative normal emptying time is, if anything, slightly longer than the normal emptying time (760 mm. before operation). The animal in B. is the only one in the entire series which showed a shortened emptying time after operation at 760 mm. and it is not significant. Note also the invariably shorter emptying time at 560 than at 760 mm. after operation (A, B and D). The dog in D. is also exceptional in that his emptying time at 560 mm. before operation was shorter than at 760 mm.

causing a pylorospasm, its motor influence on the stomach becomes manifest and causes faster than normal emptying until such severe degrees of anoxemia are reached that motility begins to suffer directly from anoxemia.

At pressures below 450 mm., such as 360, after the various operations, although the stomachs emptied distinctly slower than the postoperative normal time, they did not empty so slowly as in the corresponding tests before operation. (One dog—II in Table 1B—had such a high threshold after operation that his stomach emptied in the postoperative normal time even

ed on the basis of the complex control of the pylorus and upon the multiplicity of the stimuli produced by anoxemia. Thus, as is well known, other factors than vagus stimulation may cause pylorospasm. It is possible that more severe grades of anoxemia may cause pylorospasm irrespective of the vagi, which may be a partial cause of the delayed emptying at a pressure of 360 mm. We are inclined, however, to disregard this possibility in our experiments on unanesthetized dogs because the percentage delay at 360 mm. in the animals in which pylorospasm was prevented by pylorus section (in which emptying was solely a factor of the

motility of the stomach) was greater than those in which the pylorus was still functional but supplemented by gastro-enterostomy. Because of the consistency of our results on unanesthetized dogs, we are prepared to conclude that under mild degrees of anoxemia the delay in gastric evacuation is due chiefly to a vagospastic pylorospasm, and that under severe degrees of anoxemia a decreased motility of the stomach operates additively.

### SUMMARY

1. Studies on 23 additional dogs have entirely confirmed our previous reports showing that anoxemia causes a delay in gastric evacuation.

2. Removing, replacing or supplementing the pylorus prevents the delay caused by the less severe grades of anoxemia. This indicates that the delay resulting from mild anoxemia is due to pylorospasm. The more severe grades of anoxemia cause additional

delay probably by directly depressing the motility of the stomach.

3. The pylorospasm is on a vagospastic basis since it disappears when the vagus fibers to the pylorus are cut without disturbing those to the stomach. Atropine cannot be used for this demonstration because it simultaneously depresses the motility of the stomach.

4. After removal or denervation of the pylorus mild anoxemia may cause faster evacuation because the vagospastic effect on gastric motility now becomes manifest. However, the postoperative normal emptying time is not shorter than the normal (760 mm.).

5. We conclude that the delay in gastric emptying time during anoxemia is at first, i. e., until a critical threshold is reached, upon a vagospastic pylorospastic basis. After this threshold is passed additional delay is caused by a loss in gastric motility.

## Quantitative Estimation of Enzyme Concentration in Duodenal Fluids: A Practical Clinical Method\*

By

CHARLES W. LUEDERS, M.D.  
PHILADELPHIA, PENNSYLVANIA

THE procedure for the determination of tryptic and lipolytic activity in duodenal fluids has been greatly modified as to simplicity of method in comparison with that published by us in a previous paper (1). The first method was studied last year by the Committee on a survey of the enzyme tests as performed by members of the American Gastro-Enterological Association (2). The Committee overlooked a later article by Watson and myself, read before the Association and published in 1932(3), in which were embodied these new modifications for the estimation of tryptic and lipolytic concentration in duodenal fluids. In theory the newer method will later be shown to better satisfy essential laws of enzyme action; in practice, over a period of four years, it has proved itself a simple, rapid clinical method, which confines accurate normal values within narrow range, provides a sharp division between high and low concentration, and records abnormal values in diseased states, especially of the pancreas, liver, gall-bladder; also in

undernutrition and disorders of digestion and assimilation. The original method of amylase determination, by the estimation of maltose formed by hydrolysis of a given amount of soluble starch, using Benedict's reagent, has, with but slight modification, proved clinically satisfactory during the past fifteen years.

It is possible that a wider use of the newer method applied to normal groups may prove to other clinicians its value, and eventually overcome the objection of the Committee to the older method when they state (2): "The Lueders system is more accurate, relatively simple, but may be objected to on theoretical grounds." The newer method is in fact a modification by Hollander (5) of our previous method. It is accepted by me as such.

In my own opinion the chief theoretical objection to our previous method for trypsin and lipase determinations, was the attempt to record quantitatively the amount of amino and fatty acids formed in an hour's digestion period in terms of the number of c. c. of N 10 Na OH required to restore neutrality to the mix-

\*From the Laboratory and Gastro-Intestinal Clinic of the Pennsylvania Hospital.  
Submitted January 21, 1934.

ture. Now the "factor of reversibility of reaction" during hydrolysis by enzymes is most important, since enzymes like trypsin and lipase combine with the end products of the substrate, (combined amino and fatty acids), and act in opposition to the initial reactions. These two opposing processes of hydrolysis and synthesis act to produce an equilibrium. In the hydrolysis of starch by amylase, the "factor of reversibility" is negligible but instead a direct linear proportionality exists between the amount of enzyme present and the amount of hydrolysis effected.

The newer method set forth below rules out the factor of reversibility of reaction during hydrolysis by trypsin and lipase through an estimation of *concentration* rather than *amount*, and expressed in minutes or fractions thereof required for the neutralization of 1 c. c. of tenth normal sodium hydroxide by the amino and fatty acids formed by the hydrolysis respectively of gelatin and olive oil emulsions. Trypsin and lipase are both active in a neutral or slightly alkaline substrate. The addition of the 1 c. c. of tenth normal sodium hydroxide does not change the hydrogen ion concentration of the mixture sufficiently to inhibit the enzyme except in very low concentration. The technic takes into consideration this possibility and I believe avoids it. The time required for the formed amino and fatty acids to neutralize the added sodium hydroxide is inversely proportional to the concentration of the hydrolyzing enzymes trypsin and lipase. This result may readily be checked by using 4 different amounts of the same sample of duodenal fluid i. e. 1 c. c.; 0.5 c. c.; 0.25 c. c.; 0.125 c. c. added to each of 4 tubes of proper neutral substrate with a further addition of 1 c. c. of decinormal sodium hydroxide. The time required to change the deep phenolphthalein red to neutral (with a control) will be found to be in inverse ratio to the amount of the duodenal fluid (1 c. c. or less), or in other words in inverse ratio to the concentration of the enzyme.

It was Bayliss (4) who first stressed the universal rule found to govern the action of the hydrolyzing enzymes, namely the "Time Law" of Hedin: "To obtain the same effect with varying amounts of an enzyme, the time of digestion must vary inversely with the concentration of the enzyme." Hollander (5) applied this law in a modification of our method during 1930 and stated: "In quantitative determinations of reversible reactions especially it is more accurate to measure the time taken to effect a definite change than the amount of change in a definite time." As mentioned above the "Time Law" of Hedin does not apply to the quantitative estimation of amylolytic activity.

This modified technic was first applied by me during a study of the effect of insulin injections upon pancreatic enzymes in malnutrition. (3). Tests for the separate enzymes will here be set up in procedure form so that they may more readily be followed by the clinician or his assistant.

#### PROCEDURE

*Collection of Samples.* Follow the regular Lyon technic for duodenal drainage with a few departures as here outlined:

1. Patient must not swallow saliva during test. Provide small pus basin.
2. Extract gastric contents. Test for free HCl. If the addition of 1 drop of Topfer's reagent fails to produce a deep red color to gastric extraction, introduce through

tube 100 c. c. of 0.5 per cent HCl (to attempt to destroy salivary amylase). Retain 5 minutes, patient recumbent.

3. Then permit gravity return flow of the acid and gastric juice throughout the 20 minute gradual swallowing of tube to the 70 cm. mark.

4. If possible never use syringe for collection of duodenal samples; gravity return the safe and correct method.

5. When tube has passed to the 70 cm. mark, a bile tinged fluid (duodenal residue) should appear. Collect in small test tube surrounded by ice. If free HCl is present discard at once, then allow drainage to flow into fresh tube; repeat until sample contains no free HCl. Collect 10 c. c. of a crystal clear sample. If unsuccessful, pass 50 c. c. of hot water through tube, permit immediate return, which frequently effects a bile stained duodenal fluid return. Mark sample "A". Keep on ice until tested.

6. Give a half stimulation: 37.5 cc. of 33 per cent  $MgSO_4$ . Clip tube, wait 5 minutes. When return flow becomes dark coffee and crystal clear collect 10 c. c. in tube surrounded with ice. Mark tube "B". Collect sample "C" in same manner. If returns are cloudy turn patient on back.

7. Discard all samples that have free HCl or a total acidity of over 0.2N/10. Estimate enzymes at once, keeping tubes surrounded by ice. Or keep in Ice Chest.

*Tryptic Activity.* Trypsin is estimated as to concentration and expressed in minutes and fractions thereof, required for 0.5 c. c. of duodenal fluid to neutralize 1 c. c. of N/10 Na OH, when both are added to a neutral emulsion of 5 per cent gelatin (rendered pink with phenolphthalein as indicator. (a1) A normal tryptic activity will, within five minutes, produce amino-acids sufficient to render neutral the mixture, with loss of pink coloration.

1. Add 25 c. c. of neutral 5 per cent emulsion of gelatin to each of four large test tubes marked "A", "B", "C" and "X". "X" is the control. To the latter add 1 c. c. of boiled duodenal fluid of either "A" or "B" fraction. (Heat destroys enzyme).

2. Place in transparent water bath (\*) preferably with copper tube rack, above microburner. Maintain temperature of solutions in tubes between 37 and 40° C.

3. Add the exact amount of N/10 NaOH to equalize the low acidity of 0.5 c. c. of the duodenal fluid samples "A", "B" and "C".

4. Add 0.5 c. c. of each duodenal fluid sample to the proper tube. Note the exact time for each addition.

5. Remove each tube, place palm over end, shake and return quickly to waterbath.

6. Add 0.5 c. c. of N/10 NaOH to tubes "A", "B" and "C" and shake.

7. When dark pink changes to light pink add final 0.5 c. c. of N/10 NaOH to each tube and shake.

8. Note the exact time when the pink color disappears from the three solutions, or tends to match the solution in the control tube "X".

9. Subtract starting times in Step No. 4 from neutralization times in Step No. 8. Concentration of tryptic activity for each sample is expressed therefore in minutes and fractions thereof, and is inversely proportional to the time; i. e. the shorter the time, the greater the concentration.

*Lipolytic Activity.* Lipase is estimated as to its concentration and expressed in minutes and fractions thereof required for 0.1 c. c. of duodenal fluid to neutralize 1 c. c. of N/10 NaOH, when both are added to a neutral emulsion of 20 per cent olive oil (b2), rendered pink with phenolphthalein (1 per cent alcoholic solution) as indicator. A normal lipolytic activity, will within five minutes or less, produce fatty acids sufficient in concentration to render the solution neutral or free from the pink coloration.

\*For a transparent water bath use a 2 to 4 liter pyrex beaker; insert a circular copper test tube rack with holes to support 6 or more large test tubes of at least 5 cc. capacity. Set on high tripod above a microburner. Temperature of 37 to 40° C in the test tube may also be maintained by the addition of hot water to the water bath, as required.

tion. If neutralization takes longer than five minutes 0.5 c. c. of duodenal fluid instead of 0.1 c. c. is used but the reduced time figures are multiplied by five.

1. Add 25 c. c. of neutral emulsion of 20 per cent olive oil to each of four tubes marked "A", "B", "C" and "X". "X" is the control. To the latter add 1 c. c. of boiled duodenal fluid of either "A" or "B" fraction. (Heat destroys enzyme.)

2. Place in transparent water bath, preferably with copper tube rack, and keep temperature of solutions between 37 and 40° C. with micro-burner.

3. Add the exact amount of N 10 NaOH to equalize the low acidity of the duodenal fluid. (Estimate exact amount by testing acidity of 1 c. c. of the sample, and add to solution one half of reading if 0.5 c. c. of duodenal fluid is used). Make no adjustment for 0.1 c. c. duodenal fluid.

4. Add 0.1 c. c. of duodenal samples to proper tubes, shake and return to bath. Note exact time that each duodenal sample is added to substrate.

5. Wait three minutes exactly. (See note 3 below). Pink color may disappear.

6. Add 0.5 c. c. of N 10 NaOH to tubes "A", "B" and "C". A deep pink color may appear.

7. When mixture completely loses its pink color, add the final 0.5 c. c. N 10 NaOH and shake.

8. Note exact time when color in each of the "A", "B" and "C" tubes matches the color of the control tube "X".

9. Subtract starting times in Step No. 4 from neutralization times in Step No. 8. Concentration of lipolytic activity for each sample is expressed in minutes and fractions thereof.

*Note 1.* If neutralization time is 10 minutes or over, repeat the test but use 0.5 c. c. of duodenal fluid, and multiply the shorter time figure by five.

*Note 2.* If upon addition of the second 0.5 c. c. of N 10 NaOH no pink coloration recurs, the ferment concentration is less than three minutes. Repeat the test adding the 2 half portions of the 1 c. c. of N/10NaOH within the first minute of digestion.

*Note 3.* This method has shown that lipase is about five times more active than trypsin, hence the use of but 0.1 c. c. duodenal fluid. Lipase is more sensitive to N 10 NaOH than is trypsin. When amounts as low as 0.1 c. c. of duodenal fluid are tested, one can conceive of a dilution of ferment so great that 1 c. c. of N/10 NaOH might weaken its activity, or even destroy it, even aside from the inhibiting power of the increased pH. The three minute wait permits the ferment to act in a neutral or weakly acid mixture (formed fatty acids). Although many duodenal fluids have a lipolytic ferment in high concentration, i. e. in only 0.1 c. c. of duodenal fluid, a larger study of normals may bring a further modification in the technic, namely, the use of 0.5 c. c. of duodenal fluid for both tryptic and lipolytic activity.

*Amylolytic Activity.* Amylase is determined quantitatively by estimating the maltose formed by the action of 1 c. c. of duodenal fluid on 20 c. c. of a 5 per cent solution of potato starch (c3) made neutral or faintly pink with phenolphthalein (0.2 per cent alcoholic solution) as indicator. The end point is yellow white to a light gray. Past the end point a deepening pink appears. Since the above amount of substrate contains one gram of starch, the total amount of maltose formed in one hour will be a fraction of a gram. Bergeim (6) states that actual hydrolysis seldom exceeds 80 per cent of the theoretical 1.056 gms. of maltose in 1 gm. of starch. Willstätter considers 75 per cent the limit of saccharification.

In the Conversion Table for Total Maltose, normal hydrolysis of starch by this test, may be judged to lie

TABLE I  
Conversion for Total Maltose

| Normal Hydrolysis     |                      | Poor Hydrolysis      |                      |
|-----------------------|----------------------|----------------------|----------------------|
| Buret. reading in cc. | Maltose in Gm. and % | Buret reading in cc. | Maltose in Gm. and % |
| 0.3*                  | 0.99                 | 1.1                  | 0.27                 |
| 0.4                   | 0.74                 | 1.2                  | 0.25                 |
| 0.5                   | 0.60                 | 1.3                  | 0.23                 |
| 0.6                   | 0.50                 | 1.4                  | 0.21                 |
| 0.7                   | 0.42                 | 1.5                  | 0.20                 |
| 0.8                   | 0.37                 | 1.6                  | 0.19                 |
| 0.9                   | 0.33                 | 1.7                  | 0.17                 |
| 1.0                   | 0.30                 | 1.8                  | 0.16                 |

\*The conversion of 1 gm. of starch to 0.99 gm. of maltose is exceptional. Readings lower than 0.3 cc. would suggest the presence of salivary amylase or intestinal maltase in sufficient quantities to vitiate this or any method based on determination of reducing sugar. (6).

within the figures of the first maltose column; poor hydrolysis within the figures of the second column.

The most valuable and instructive work upon comparative tests for pancreatic amylase is that of Schmidt, Greengard and Ivy which appeared recently in this Journal (6). Constructive criticism of our method as first applied is merited; however modifications over the past ten years have corrected most of them.

The possible advantages of this test and its technic over other recommended tests is 1. simplicity; 2. reagents more commonly in use in most laboratories; 3. and of essential importance: the recognition that salivary amylase is still active in duodenal fluids in cases of hypochlorhydria and achylia; 4. the technic tends to reduce this serious complication to a minimum. A possible disadvantage: The end point, always a clear cut change from the Benedict reagent blue to a yellow or grayish white, is frequently shortened as further substrate is added, producing a deepening pink.

Bergeim (7) confirms my own doubts about the value of any test for pancreatic amylase in cases of achylia. The latest writers who recommend the newer tests for pancreatic amylase do not seem to have considered the question of saliva. In Bergeim's words: "the gravest criticism of any method for estimating pancreatizing amylase" . . . "It is on this account, evidently, that it is necessary to determine trypsin and lipase."

#### Procedure.

1. Add 20 c. c. of the 5 per cent starch solution (c3) to each of three large test tubes marked "A", "B" and "C". Also the same amount to control tube "X".

2. To each tube add one drop of 0.2 per cent alcoholic solution phenolphthalein. (\*) Then add, drop by drop, N 1 NaOH until a light pink color is produced which persists on shaking. 1 or 2 gts. usually.

3. Now add to each tube, drop by drop, from a burette, N 10 H<sub>2</sub>SO<sub>4</sub> until the first disappearance of the pink color. (\*\*). Immerse tubes in hot water until solutions are heated to 37° C.

4. Add 1 cc. of each duodenal fluid sample to the proper "A", "B" and "C" tube. Add 1 cc. of boiled "B" sample to Control tube "X". Incubate tubes for one hour at 37°C., shaking the tubes every 15 minutes.

5. Upon removal from incubator add to tubes "A", "B"

(\*) Note. Dr. Bergeim advises the weak solution of phenolphthalein to insure an exact end point, and avoid the deep red color after the gray-white.

(\*\*) Note. The pH for maximum activity of amylase is on the acid side of neutrality or 6.5. The loss of pink color with N/10 H<sub>2</sub>SO<sub>4</sub> indicates (approximately) neutrality (pH 7.4); the addition of the weakly acid duodenal fluid gives a still lower pH concentration sufficiently accurate in practice to permit maximum amylolytic activity. pH 7.0 by test.

TABLE II  
Normal Findings for Trypsin and Lipase in 35 Normal Subjects (Hollander)

| Patient                | Lipase<br>Minutes | Trypsin,<br>Minutes |

| I. G.                  | 1½                | 1½                  |
| Repeated 1 day later   | 2                 | 2                   |

and "C" a small amount of sodium carbonate (about 5 grains), to stop digestion.

6. Pour a portion of each digestion mixture into its proper 2 c. c. pipette, (used as a burette), and graduated in tenths, and run slowly (0.2 c. c.), then drop by drop, in 5 c. c. of Benedict's reagent (d4) plus 1-2 gms. of sodium carbonate (½ in. of spatula) heated to boiling in 25 c. c. Erlenmeyer flask, over micro burner. (Add previously a pinch of powdered talc to prevent bubbling).

7. End Point. Boil *gently* until the last blue color disappears and changes to yellow or slate gray, and before the gray changes to pink the end point is reached.

8. Result. Expressed quantitatively in terms of maltose. The burette reading divided into 0.0149 (the number of grams of maltose to reduce 5 cc. of Benedict's reagent) gives the amount of maltose in 1 cc. of the digestion mixture. Multiply by 20 to obtain the total amount of maltose formed from 1 gm. of starch. (See conversion table above).  $0.0149 \div \text{burette reading} \times 20 = \text{gms. of maltose.}$

a1. 5 Per Cent Gelatin Emulsion. Dissolve 25 grams of sheet-gelatin\* in 300 c. c. distilled water in 500 c. c. pyrex flask set in a water bath. Raise temperature gradually until gelatin is perfectly dissolved and clear. In a mortar place 12.5 gms. of gum acacia (purest grade), add gradually 50 c. c. of liquid albolene, rub into a smooth paste, then add all at once, 25 c. c. of distilled water and continue stirring in one direction until a milk white emulsion is formed. To this add the 300 c. c. of melted gelatin. Pour into a graduated cylinder. Make up to 500 c. c. with washings of mortar and warm distilled water, and 2 c. c. of 1 per cent alcoholic solution of phenolphthalein made neutral with normal NaOH. Shake well, then distribute into 100 c. c. storage flasks. Cover the emulsion in the flasks with a thin layer of toluene; store in ice chest. When needed liquify by gentle heat in water bath; (a temperature of 60° C will scorch gelatin). "Shake well" label on

flasks, to insure an even emulsion before measuring into test tubes marked 25 c. c.

b2. 20 Per Cent Olive Oil Emulsion. Place 25 gms. of gum acacia (purest grade) in a mortar; add gradually 100 c. c. of highest quality olive oil; rub into a smooth paste; then add all at once 50 c. c. of distilled water, and continue stirring in one direction until a milk white emulsion is formed. Add more distilled water; make up to 500 c. c. in a graduated cylinder, using washings of mortar with distilled water. Pour into a 500 c. c. flask. Add 2 c. c. of 1 per cent alcoholic solution of phenolphthalein and make neutral (faint pink) with Normal NaOH (about 1.5 c. c.). Shake Well Label on flask, to insure an even emulsion before pipetting into test tubes. Keep in ice chest. A 50% emulsion is more stable. See "Equipment."

After considerable experiment it was found that dependable results were obtained only with freshly prepared oil emulsion. Formaldehyde as a preservative was not satisfactory; toluene with the oil emulsion gave larger figures for time or negative results. Sterilization also proved unsatisfactory. 20% emulsion stable 1 mo. 50% much longer.

c3. Starch Solution (5 per cent). Stir 25 gms. of Merck's soluble starch (Lintner) into a smooth paste in a mortar by adding slowly 30 c. c. of cold distilled water. Heat to boiling 470 c. c. of distilled water in a 500 c. c. sterile pyrex flask. Pour gradually into starch paste, stirring continuously to insure a mixture free from lumps. Pour the solution back into the warm pyrex flask. Add five milligrams of mercuric iodide to the 500 c. c. mixture (10 mgm. to the liter), as a preservative. It is preferable to the toluene previously used; it prevents lumping of the starch. May be kept on ice or at room temperature.

d4. Benedict's sugar reagent

Copper sulphate (crystallized)..... 18.0 grams  
Sodium carbonate (crystallized) (one half the weight of the anhydrous salt may be used)..... 200.0 grams  
Sodium or Potassium citrate..... 200.0 grams  
Potassium thiocyanate..... 125.0 grams  
Potassium ferrocyanide (5 per cent solution) ..... 5.0 cc.  
Distilled water to make a total volume of ..... 1000.0 cc.

With the aid of heat dissolve the carbonate, citrate and thiocyanate in enough water to make about 800 cc. of the mixture and filter if necessary. Dissolve the copper sulphate separately in about 100 cc. of water and pour slowly into the other liquid with constant stirring. Add the ferrocyanide solution, cool, and dilute to exactly 1 liter. The copper salt only, need be weighed with exactness.

Duodenal Juice Of Highest Concentration. The above technic allows for the testing of the three duo-

| 2.       | 20               | 12              | 0                | 16 $\frac{1}{2}$ | 10 $\frac{1}{2}$ | 30              | 0.15                  | 0.10 | 0.00 |
| 3.       | 49               | 0               | 20               | 27 $\frac{1}{2}$ | 12               | 4 $\frac{1}{2}$ | 0.30                  | 0.15 | 0.25 |
| 4.       | 3 $\frac{1}{2}$  | 5 $\frac{1}{2}$ | 13               | 4 $\frac{1}{2}$  | 4 $\frac{1}{2}$  | 4 $\frac{1}{2}$ | 0.35                  | 0.25 | 0.27 |
| 5.       | 10               | 15              | 12               | 3 $\frac{1}{2}$  | 3 $\frac{1}{2}$  | 3 $\frac{1}{2}$ | 0.35                  | 0.23 | 0.21 |

denal fractions, "A", "B" and "C". Friedenwald, Einhorn and Bockus agree that the fasting duodenal juice represents the highest point of enzyme concentration. Hollander found the specimen having the deepest color following the instillation of 33 per cent magnesium sulphate solution contained the pancreatic ferments in highest concentration. After reviewing the hundreds of tests performed before the final procedure was accepted as of clinical value, I find that sample "C" contains usually ferments of lower concentration; that sample "B" (darkest colored fluid after salt stimulation) and sample "A" (duodenal residue or common duct fluid or their combination) are equally rich in pancreatic ferments; but for clinical work I prefer sample "B", and for two reasons: 1. less possibility of salivary amylase; 2. the increased bile salts in the "B" mixture insures maximum activation of lipase and protection of amylase from destruction by trypsin. Granted that magnesium sulphate stimulates the secretion of intestinal maltase this factor of error in any test for pancreatic amylase is of minor importance as compared with the likely presence of salivary amylase in duodenal residue, (sample "A").

*Normal Values Of Enzyme Concentration.* To judge the value of a method for estimation of ferment activity, figures established as normal should have been derived from tests upon normal subjects. Normal figures should be confined within narrow limits. The method should reveal a sharp division between the high concentration of enzymes in health and the low concentration of the same enzymes in certain diseases, especially of organs concerned in the functions of digestion, assimilation and nutrition. The Committee

"on survey of enzyme tests etc." of the American Gastro-Enterological Association has asked certain members of the Association to compare the Willstätter method for estimation of amylolytic activity with the Lueders method, by estimating the amylase in the duodenal contents on twenty normal individuals, or persons known not to have diseases involving the G-I tract, applying both methods. Trypsin and lipase concentration, using our own method, will be estimated at the same time the above request of the Committee is carried out in our own group.

The five minute limit for normal concentration of lipase and trypsin using but 0.1 c. c. of duodenal fluid for lipolytic activity, and but 0.5 c. c. for tryptic activity very effectively isolates all duodenal fluids with low concentration. In my own experiments upon patients with diseases of the digestive tract and with those suffering from undernutrition, few of them consistently recorded a figure within the 5 minute limit. Hollander's findings were as striking. I shall include a table of figures of enzyme concentration for trypsin and lipase in his normal subjects using this modification of our first method, the same modification I have applied for the past four years, and the technic of which is presented above.

As for the accuracy and practical value of the amylase quantitative test first applied by us in 1922, so many preliminary studies were made on duodenal fluids from healthy subjects as well as patients with diseases of the G-I tract, that it was then established that 1 c. c. of duodenal fluid in health should convert 1 gm. of potato starch, incubated at 37° C, into maltose, to the extent of 0.8 gm. Patients suffering from

TABLE V  
Enzyme Concentration in Cases With G-I Tract Disorders or Diseases

| Case No. | Diagnosis                                 | Trypsin, Minutes |                 |                 | Lipase, Minutes |                 |                 | Amylase, maltose gm. |     |     |

|          |                                           |                  | 6 $\frac{1}{2}$ |                 |                 | 20 --           |                 |                      | .42 |     |

digestive tract disorders did not give that percentage of hydrolysis. Therefore figures below 0.3 gm. of maltose are considered abnormal.

After years of personal experience with enzyme tests in the chemical laboratory, hospital and office, I am willing to predict that no routine ferment analyses will become popular with the internist unless it proves simple in method and materials, rapid in technic and whose sufficient accuracy is dependent not so much upon complicated buffers, optimum pH, and formulae as upon the expression of a mean between necessarily wide fluctuations of enzyme concentrations in the heterogeneous mixture known as duodenal fluid.

### COMMENT

In spite of the fact that normal values for enzyme concentration were occasionally found in one or more of the duodenal fractions of the diseased group, it was rare to obtain normal concentration of the three enzymes as in the normal groups. As revealed in Table 4, although five cases are too few on which to base conclusions, it is of interest that in each case of diabetes the pancreatic amylase was low in amount, and in every extraction of duodenal fluid. I repeat, that the above methods applied clinically during the past four years have restored a faith in the clinical value of routine pancreatic ferment estimations, which all previous methods, including our own, had well nigh destroyed.

### CONCLUSIONS

Methods are described for the determination of trypsin, lipase and amylase in duodenal fluids. Modification by Hollander of our previous methods for estimation of tryptic and lipolytic activity has proved of distinct value during the past four years of its application. The test for amylase, with but slight modification, has proved satisfactory during the past fifteen years. Any clinician trained in the Lyon technic of non-surgical duodenal drainage should find the above methods simple, rapid and sufficiently accurate. As soon as some such practical procedure for the estimation of pancreatic enzymes in duodenal fluids has been widely accepted as reliable it may well give fresh impetus to further investigation of secretory dysfunction and diseases of the pancreas. It should also prove a valuable routine addition to the diagnostic survey of patients with any disease involving the G-I tract as well as those with disorders of nutrition, digestion and assimilation.

I wish to here express my sincere appreciation of the valuable advice and criticism by Dr. O. Bergeim, in re-

cent correspondence as to improvements in our amylase test. Also heartfelt thanks to Miss M. E. Watson for her kindness in her latest check up of all the data accumulated during the application of the above methods upon hundreds of duodenal fluids studied in 1931.

### EQUIPMENT FOR TESTS

#### Glassware

- ½ doz. small test tubes (½ in. diam.)
- ½ doz. large test tubes (1 in. diam.)
- ½ doz. small beakers (250 cc.) (or drinking cup or glass)
- One large Beaker, Pyrex (2-4 liter)
- ½ doz. small Erlenmeyer flasks (50 cc.)
- 2 CC. Pipette (graduated in tenths cc. Use as burette)
- 2 Pipettes, volumetric (25 cc.)
- 1 Pipette, volumetric (5 cc.)
- 1 CC. Pipette, graduated in tenths cc.)
- 1 Cylinder (250 cc. graduated)

#### Chemicals

- Phenolphthalein 1% and 0.2% (alcoholic sol.)
- NaOH, N/10 and N/1
- HCl, (USP.) To make 0.5% sol.
- Sodium Carbonate
- Powdered Talc
- Benedict's Reagent
- Gelatin (5 per cent emulsion)
- Starch (5 per cent solution)
- Olive Oil (20% emulsion) (\*) (Last four solutions prepared as described in body of paper)
- H<sub>2</sub>SO<sub>4</sub>, N/10

#### Miscellaneous

- 1 Copper circular test tube rack
- 1 Tripod (high) to support large Beaker
- 1 Micro-burner
- 1 Centrigrade thermometer
- 1 Glass dropper tip, rubber tube and clip to attach to end of 2 cc. Pipette
- 1 Small Incubator (gas or electric)

*Note.* Most of the miscellaneous equipment may be dispensed with, if the clinician has a large pitcher of hot water available to keep adding to the water, in the large beaker, surrounding the digestion mixtures so that the temperature in each test tube is maintained at 37 to 40° C for the duration of the test.

*Note\*:* Olive Oil Emulsion (50%) machine made, may be purchased from Abbott Laboratories, North Chicago, Ill. Preferred by Dr. Crandall in his Lipase test (8). Also from J. Wyeth & Bro., Phila. If 50% Emulsion is used, 10 c. c. is diluted to 25 c. c. with distilled water for test.

# The Origin and Significance of the Blood Serum Enzymes\*

By

LATHAN A. CRANDALL, Jr., M.D., Ph.D.  
CHICAGO, ILLINOIS

THE value of the quantitative determination of blood (serum) enzymes, especially amylase (diastase), in the diagnosis of pancreatic disease has been established. There are also many reports in the literature on the use of other enzyme determinations as aids in diagnostic procedure; in most cases these have not been adequately confirmed and their value is speculative. Our knowledge of the origin, fate, and significance of the serum enzymes in health and disease is fragmentary, and for the most part is based upon assumptions rather than conclusive evidence. In many cases we cannot even be certain of the significance of changes which are well beyond the limits of normal. Certain confusions in terminology and a multiplicity of methods have produced conflicting reports; to this is added a lack of established normal standards, due largely to technical difficulties.

A review of those facts which are of practical significance will therefore be presented, together with certain pertinent experimental data.

## THE ENZYMES OF NORMAL BLOOD

Blood serum is known to contain ferments acting upon the three major classes of foodstuffs: carbohydrates, lipoids, and proteins. The enzyme acting upon carbohydrates is the starch and glycogen splitting ferment termed amylase or diastase; it seems probable that more than one type of amylase is present. Sera from animals of different species certainly show wide variations in their ability to attack various starches (1). In man, variable results are obtained, depending upon whether one studies the ability of the enzyme to produce sugars, its capacity to split the starch to the point where iodine no longer gives a blue color, or the change in viscosity brought about in a starch solution. Until more conclusive evidence is available concerning the nature of these enzymes, and the fractions of starch which they attack, it will probably be most satisfactory to refer to the reducing sugar producing enzyme as "saccharogenic amylase," and to that which causes the change in viscosity as "liquefying amylase."

The general term "esterase" signifies those enzymes capable of hydrolyzing the ester linkage. It covers the group that attacks such various compounds as ethyl butyrate, tributyrin, true fats and oils, cholesterol esters, lecithin, and the waxes. An esterase or esterases acting upon ethyl butyrate are present in blood and in all tissues examined (2). The word "lipase" is often used synonymously with esterase, or may be restricted to the enzyme (or enzymes) capable of splitting true fats and oils at the ester linkage. Since the oil splitting ferments have been shown to be quite distinct from those hydrolyzing the simpler esters, it is

perhaps best to use lipase in the second, more limited, meaning. In this sense there is seldom any appreciable amount of lipase (active on fats and oils) in normal human sera, although as will be noted later it may be present in certain pathological conditions. The esterases which are present in blood and which act upon ethyl butyrate or tributyrin are inactive upon true fats or oils such as olive oil. Confusion in the nomenclature of the lipolytic enzymes is probably best avoided by employing a term suggestive of the specific substrate used, i.e., "lecithinase," "ethyl butyrase," "tributyrinase," etc., reserving *lipase* for the enzymes active on neutral fat (triglycerides of the higher fatty acids).

Relatively little attention has been paid to the proteases of the blood. The determination of the proteolytic activity of serum is complicated by the presence of anti-proteases. Recent studies (3) have shown that accurate determination of serum proteases is possible only when they have been adsorbed on a protein and thus freed from anti-proteases. Since no clinical studies of the serum proteases in which this factor is considered have been encountered in the literature, a discussion of these enzymes is not pertinent to the material presented herein.

In addition to the three classes of enzymes mentioned above, the blood contains phosphatase, catalase, histaminase, possibly maltase, and a number of other specific enzymes. With the exception of phosphatase little is known of the variations of these ferments in pathological conditions. The increase in serum phosphatase that occurs in diseases of the bone has been shown to be of diagnostic value (4).

## METHODS

A detailed discussion of the methods employed in the estimation of blood enzymes is not within the province of this article. It should be emphasized, however, that many of the apparently contradictory results reported in the literature may be explained by variations in the procedures used by different investigators.

In the case of the amylases the method of Wohlgemuth (5), which depends upon the failure of starch to give a blue color with iodine after hydrolysis, has been frequently employed. This procedure is subject to rather large variations, depending upon the technique and color judgment of the individual, and the starch sample used as the substrate. It has therefore been largely supplanted by less subjective methods, notably the viscometric (determination of viscosity changes in an autoclaved starch substrate) which was first applied to amylase by Davison (6), and the group of methods that depend upon determination of the reducing sugar liberated from starch. The two latter methods are approximately equal in accuracy, although

\*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Illinois.  
Submitted March 15, 1935.

both require considerable attention to the elimination of interfering factors. The evidence in the literature suggests that either different enzymes or different properties of the same enzyme are measured, depending upon whether one estimates the early stages of starch hydrolysis (viscometric or Wohlgemuth methods) or the amount of end products formed (reducing sugar liberated).

Even when only one method is employed, differences in the type of starch used as substrate will produce considerable variation in the results (7). This may be due to varying amounts of amylose, amylopectin, and dextrins in the starch sample. According to Somogyi (8) the amylase of blood serum splits starch chiefly to tri-saccharides which have reducing properties, only a small amount of maltose being formed. He states that maltase does not appear to be present in serum. In view of the differing reducing powers of glucose, maltose, and tri-saccharides, the presence or absence of maltase and of enzymes which split the tri-saccharides may introduce appreciable errors in the determination of saccharogenic amylase. In the determination of liquefying amylase by the viscometric

TABLE I

*Lipase and diastase in portal and saphenous blood after intravenous injection of 30 cc. pancreatic juice. London cannula on portal vein*

|                           | Saphenous |          | Portal |          |
|---------------------------|-----------|----------|--------|----------|
|                           | Lipase    | Diastase | Lipase | Diastase |
| 1:00                      | 0.0       | 9.       | 0.0    | 10       |
| Injected pancreatic juice |           |          |        |          |
| 1:15                      | 1.0       | 61       | 1.7    | 69       |
| 1:45                      | 1.0       | 40       | 1.5    | 48       |

method the presence or absence of ferments which attack maltose or trisaccharides is of course immaterial. With all amylase methods, however, considerable variation in results will appear unless precautions are taken to keep the substrate constant in composition or to determine the effect of substances which may be present in solution with the enzyme. It is especially important to maintain the pH and salt concentration constant.

In order to insure uniformity of results when various lots of substrate must be used, a simple and reliable procedure is to take advantage of the stability of enzymes in 50% glycerin. A preparation of ground pancreas, pancreatin, or pancreatic juice in 50% glycerin will usually remain constant in activity for several months; one such preparation of pancreatin kept in

the icebox showed no change over a period of two years with regard to its lipase content. Amylase is similarly stable in glycerin. Such a preparation may be used as a standard, for the comparison of various lots of substrate. In any event the arbitrary "units" which must be employed in expressing enzyme activity will usually vary from one laboratory to another, due to unavoidable variations in the substrate.

The methods for the determination of the esterases usually involve titration of the fatty acids set free by action of the enzyme on the substrate in the presence of a buffer. The principal variation in the results obtained by different workers is due to the different substrates employed. Many workers have considered the enzyme which attacks ethyl butyrate or tributyrin to be identical with that which hydrolyzes the true fats, and have used the term "lipase" for both. Cherry and Crandall (7) have recently shown that these two enzymes are quite distinct, and have suggested that the term "esterase" be employed for the former, "lipase" for the latter. The blood ordinarily contains appreciable amount of esterase but little or no lipase. The amount of esterase (ethyl butyrase) in pancreatic juice is not far from that in the blood, but this secretion contains relatively enormous amounts of lipase (olive oil substrate). When the pancreatic ducts are ligated the esterase content of the blood may rise or fall slightly or may not change, while lipase appears in the blood in large amounts. Since many workers have employed ethyl butyrate or tributyrin in the determination of lipolytic activity in pancreatic juice or duodenal drainage, statements concerning the "lipase" activity of these fluids must be interpreted on the basis of the method employed. Esterase is an ubiquitous enzyme, occurring in every tissue examined. Lipase is not present in striated muscle, brain, lung, or blood serum; the liver and spleen contain a small amount, the pancreas yields the greatest quantity, and intestinal mucosa is intermediate. There is no reason to assume that esterase is manufactured by the pancreas, the amounts found in pancreatic juice might well be present in any secretion formed from the blood plasma. The high concentration of esterase found in the liver suggests that this organ is the chief site of its formation. On the other hand, the pancreas may with equal logic be presumed to generate lipase, although no inference can be drawn regarding the ability of other organs to form this enzyme.

#### THE RELATION OF BLOOD ENZYMES TO PANCREATIC FUNCTION

The significance of blood amylase in the diagnosis of pancreatic disease has been the subject of many reports; the literature has been reviewed recently by

TABLE II

*The effect of injecting secretin intravenously on the serum lipase and diastase in Eck fistula dogs. One unit secretin equals minimal amount necessary to obtain a response from the pancreas of a normal dog.*

| Secretin |            | Control |        | 45 min. |     | 2 hrs. |     | 3 hrs. |     | 4 hrs. |     |
|----------|------------|---------|--------|---------|-----|--------|-----|--------|-----|--------|-----|
| Dog      | Units inj. | Lipase  | Diast. | Li.     | Di. | Li.    | Di. | Li.    | Di. | Li.    | Di. |
| E 28     | 80         | .2      | 11     |         |     | .7     | 13  |        |     | .1     | 10  |

McCaughan (9) who also presents animal experiments illustrating the enormous rise of the blood amylase after pancreatic injury or obstruction of the pancreatic ducts. McCaughan employed the viscometric method, which because of its sensitivity and accuracy has been largely used by workers in this field. He points out that the normal range for amylase is relatively narrow. Many workers have noted the tendency of the blood amylase to return to the normal value within about two weeks after ligation of the ducts. Gould and Carlson (10) also described secondary and even tertiary rises so that the blood amylase may be above normal even 2½ months after complete duct ligation. A number of recent workers have suggested that blood enzyme determinations in the presence of pancreatic disease can be expected to be significant only within a brief period after injury, because of the rapid return to normal in animals under similar conditions. This statement is apparently based upon experiments that have been continued only until the first return of the blood enzyme to normal. The fact that a second and third rise may occur suggests that the period during which blood amylase determinations may be significant is longer than has been assumed. It is nevertheless true that in the presence of chronic injury to the pancreas the blood amylase does not remain elevated. On the basis of animal experimentation one may assume that slighter degrees of pancreatic injury will produce less marked and more brief amylase elevation. If the pathological changes in the pancreas progress to fibrosis and degeneration, the blood amylase may even fall below the normal value. Thus in early pancreatic injury the amylase of the blood may be expected to be elevated roughly in proportion to the injury, normal values do not necessarily signify a normal pancreas, while a decrease in blood amylase suggests chronic pancreatic injury with cessation of enzyme formation.

The reports concerning the effect of pancreatectomy on the blood amylase in the dog are variable. King (26) and Gould and Carlson (10) found a decrease; further literature is quoted by Reid, Quigley, and Myers (28). The writer has observed abnormally low blood amylase values on depancreatized dogs (maintained on insulin and fed raw pancreas) as long as one year after operation (viscometric method). Such findings have led many workers to conclude that the pancreas is important in maintaining the blood amylase level. Reid, Quigley, and Myers (27) state that there is a tendency for the blood amylase to fall after pancreatectomy, but that normal values are restored by insulin. They further report high amylase values in uncontrolled diabetics, using in both instances a reducing sugar method. This question is of significance because it involves the interpretation of low values found clinically. Abnormally small amounts, if found by the viscometric or starch-iodine methods, may suggest deficiency in enzyme formation by the pancreas. Interpretation of amylase values based on the reducing sugar method are more difficult. Reid and Narayana (11), using this method, find that ligation of the pancreatic ducts in dogs has no effect upon the blood amylase level. Until further studies are made, the estimation of saccharogenic amylase would seem to be of doubtful value in the diagnosis of pancreatic disease.

Conditions not involving external secretory function of the pancreas, but which may alter blood amylase,

are nephritis, liver disease, and diabetes. The values found in these conditions will depend upon whether saccharogenic or liquefying amylase is determined. In no instances, however, are more than moderate increases encountered. When a marked rise in the (liquefying) blood amylase is present it must be interpreted as indicating pancreatic pathology.

It has been known since the work of Hanriot (12), Doyon and Morel (13), and Arthus (14) that normal serum contains no enzyme capable of hydrolyzing the true fats or oils, whereas the pancreatic secretion is very active in this respect. These workers also recognized the presence of an esterase (ethyl butyrase) in the blood serum. The above facts have been largely ignored. Many investigators have made the assumption that the ethyl butyrase of the blood stream is related to the lipase of the pancreas, and that like amylase it should reflect changes in pancreatic function. The fact that the ethyl butyrase of the serum shows little or no change after pancreatic injury has led to conflicting reports. As stated above, attempts have been made to study "lipase" even in the pancreatic juice by the use of ethyl butyrate as a substrate, with obviously discrepant results. It should be noted that McClure, Wetmore and Reynolds (15) introduced the use of finely emulsified and buffered cottonseed oil in the study of lipase in the duodenal drainage, with very satisfactory results. Cherry and Crandall (8) employed a similar method (finely emulsified olive oil with buffer) in the study of serum lipase. Olive oil, peanut oil, and cottonseed oil appear to be equally satisfactory; presumably any triglyceride of the higher fatty acids will serve. Crandall and Cherry confirm previous observations on the absence of lipase (olive oil splitting) in the normal serum, and appear to be the first to have shown that such a lipase is found in the blood, in relatively large amounts, after ligation of the pancreatic ducts. Ligation of the ducts produces no constant change in the esterase acting on ethyl butyrate or tributyrin as determined by the titration or stalagmometric methods. The olive oil lipase appears in the serum within 24 hours after duct ligation and returns to normal within 2 to 6 weeks, depending apparently on the degree of injury to the pancreas. It may, like amylase, show a secondary rise. Lipase is commonly present in small but definite amounts in the serum in the presence of liver pathology, recalling the tendency of serum amylase to rise under similar conditions. This phenomenon will be discussed below; it obviously complicates the value of serum lipase determinations in the diagnosis of pancreatic disease when the liver is known to be affected. It should be noted, however, that the increases in serum lipase and amylase which occur after liver injury are relatively small, never approaching the figures found shortly after acute pancreatic obstruction. Comfort and Osterberg (16) have recently investigated the serum lipase and esterase in patients with pancreatic, hepatic, or biliary tract disease. They find abnormally high values for lipase in a large percentage of patients with acute or subacute pancreatic affections, and suggest that it be further studied as an aid in diagnosis. Esterase determinations (ethyl butyrase) were found to be of no value. In view of the accuracy, simplicity, and sensitiveness of the lipase method it deserves further clinical trial in comparison with amylase in diseases of the pancreas.

The literature on determinations of serum esterase

in disease has been reviewed by Oppenheimer (17). No studies that have appeared since this review alter the conclusion that changes in blood esterase are not associated with any disease in such a manner as to permit esterase determinations to be used as a diagnostic aid.

#### THE RELATION OF BLOOD ENZYMES TO THE LIVER

Wohlgemuth in 1910 showed that ligation of the common bile duct caused a delayed but definite rise in the blood diastase. This rise did not occur if the bile duct ligation was performed some time after ligation of the upper pancreatic duct; that is, liver damage had no effect on a blood amylase which was already increased secondary to pancreatic obstruction. Falkenhäuser (18) has shown that the blood amylase increases after phosphorus poisoning in dogs and rabbits (starch iodine method). Tomioka (19) has also reported increased blood diastase values on experimental liver damage of various types in animals and in liver disease in man. Elman, Arneson and Graham (20) did not observe increased blood amylase values in human liver disease without pancreatic involvement (viscometric method). In a preliminary report Crandall and Cherry (21) have confirmed the increase in liquefying amylase following ligation of the common bile duct, and have reported that the serum amylase is frequently above the normal level in Eck fistula dogs. The same authors (22) have observed abnormally high amylase values in liver disease.

Very recently Somogyi (23), studying saccharogenic amylase, reports only abnormally low values in liver disease. This interesting apparent difference between liquefying and saccharogenic amylases, like that found for pancreatic duct ligation, requires further investigation. Such studies are in progress.

Studying the lipolytic enzymes in experimental liver damage, Crandall and Cherry (24) have reported the appearance of (olive oil) lipase in the serum following ligation of the common bile duct or production of Eck fistula in dogs, and have noted that the esterase (ethyl butyrase) is not significantly changed under these conditions. They further found appreciable amounts of lipase in the blood of eight out of ten cases of human liver disease, as compared with positive values in only 7.6% of 131 control cases which were selected at random, and in which hepatic or pancreatic damage was not ruled out except by preliminary examination (22). Since that time the author has observed significant amounts of lipase after chloroform or cinchophen poisoning in dogs. Barker (25) has also found it present in the serum after plasmapheresis or long continued low protein diets in dogs; degenerative changes are found in the liver in these animals at autopsy.

In our preliminary report on the regulation of blood diastase and lipase by the liver, Cherry and I (21) suggested that these enzymes might normally be absorbed from the gut (presumably in small amounts) and removed from the portal blood by the liver. This might explain their appearance in the systemic blood after liver injury. It is well known that the damaged liver does not remove other substances from the blood in a normal manner. Zucker, Newburger, and Berg (27) in commenting upon this report, refer to us as supposing that pancreatic damage causes secondary liver injury, with the release of lipase and diastase from the liver into the blood. We had never enter-

tained such a conception, but suggested only that a damaged liver may be incapable of normally removing enzymes from the blood.

The reason for the increased lipase and amylase values in blood in the presence of liver disease or experimental injury is obscure. That the liver takes up enzymes from the blood is indicated by the fact that the values for amylase and lipase are higher in the portal than the systemic blood after the intravenous injection of pancreatic juice (Table I). The methods used were those discussed previously (22). It is now questionable whether there is sufficient absorption of enzymes from the intestine to influence significantly the blood enzyme values; this point will be discussed below. An attempt has been made to determine whether the secretory state of the pancreas might influence the blood lipase and amylase values in the presence of liver injury. For this purpose Eck fistula dogs were given large doses of highly purified secretin, with results as shown in Table II. The changes in the blood enzymes are in the direction of a rise in every instance; however, the changes found are not definitely beyond the normal variations of the blood enzymes.

Liver injury does not increase the lipase and liquefying amylase of the blood by reducing the amount of bile entering the intestine, since bile fistula dogs show no change in blood enzymes until the liver becomes damaged by ascending infection. It seems probable that the enzymes do not originate in degenerating liver tissue. If this were the case, one would expect high values immediately after acute injury, with gradual stabilization at or near the normal level, as is the case following pancreatic obstruction. However, the rise following experimental liver damage is never great and, at least in Eck fistula animals, may be sustained for more than a year. The principal possibilities which remain are that the liver normally regulates the blood enzyme level by removing any excess, or that pathological changes in the liver produce secondary disturbances in pancreatic function. Analyses of portal and systemic blood for amylase and lipase in normal unanesthetized dogs with London cannulae on the portal vein to collect portal blood lend no support to the first hypothesis, since even after the injection of secretin no significant portal-systemic differences were noted. It is not impossible that injury to the liver may secondarily influence the pancreas, since various types of experimental liver damage are well known to affect other parts of the gastro-intestinal tract ("peptic" ulcer after bile duct ligation, biliary fistula, Eck fistula).

One must conclude that no definite hypothesis can be formulated to explain the cause of the changes in blood enzymes (increase in liquefying amylase, appearance of olive oil lipase) in the blood in liver disease and after experimental liver injury. The slight increase in diastase found in liver disease is insufficient to be of diagnostic importance. It is possible that more extensive clinical investigations would show lipase determinations to be of some value. Somogyi's (23) observations on saccharogenic amylase should be confirmed.

Bodansky and Jaffe (29) have demonstrated an increase in serum phosphatase in dogs as a result of common bile duct ligation; the maximum value after operation was approximately 80 times the normal, which "is the highest value that we have obtained in

any condition in any animal." Roberts (30) has demonstrated an increase in phosphatase in obstructive jaundice in man, which was confirmed by Bodansky and Jaffe (29) for catarrhal jaundice. Studies of serum phosphatase in the presence of pancreatic obstruction have not been found. Simultaneous determinations of lipase (olive oil) and phosphatase in hepatic and pancreatic pathology in animals and man would be of interest, since it is conceivable that changes in these two ferments might be of more value in diagnosis than is either alone.

#### THE ABSORPTION OF ENZYMES FROM THE INTESTINE

King (26) found that the administration of 17,500 units of salivary amylase to each of 2 cats daily for 4 days resulted in an increase of 6.3 and 22.4 units in the urine, respectively. This he accepted as demonstrating the absorption of this enzyme from the gut, although it was recognized that by far the greater part must be absorbed or excreted in the feces. The absorption of amylase was denied by Zucker, Newburger, and Berg (27) who introduced pancreatic juice into the duodenum and found no increase in blood amylase. They used the starch-iodine method, which is regarded by Myers and Reid (31) as unsuited for the quantitative determination of amylase because of its inaccuracy. Zucker *et al.* further believe it unlikely that this enzyme could be absorbed because they assume it to be of the nature of a protein. It is known that even proteins may be absorbed from the intestine in traces (32); furthermore, it has been stated that it is relatively easy to prepare amylase which is protein-free (33).

In view of the above facts, further experimental work on the intestinal absorption of enzymes was undertaken. In order that the enzymes might be introduced directly into the intestine, dogs were prepared with jejunal fistulae. At a second operation Eck fistulae were established in the same animals, since if the liver is active in the removal of enzymes from the blood any increase might be more easily demonstrable after liver injury. After recovery from the operation and when in good condition these dogs then received from 200 to 300 cc. of fresh active pancreatic juice or 300 cc. of saliva (human) by way of the jejunal fistula. The results (Table III) are for the most part negative, al-

amounts of enzymes seems probable. The quantity absorbed under ordinary conditions, however, can hardly be sufficient to have any influence upon the blood enzyme level.

In view of the above facts, the hypothesis of Oelgoetz, Oelgoetz, and Wittekind (34), seems untenable. These workers suggest that enzymes, absorbed from the intestine, function in the blood stream to break down incompletely digested foods which have been likewise absorbed and that when the quantity of enzymes secreted by the pancreas is relatively insufficient for adequate digestion in the gut there is no longer an excess available for absorption as a factor of safety against unsplit food products which are also absorbed. They describe a deficiency in the serum enzymes of patients with food allergy who have been given extraordinarily large meals, and believe that the allergy may be due to the enzyme deficiency. Many studies have been made on the relation of the blood enzymes to various phases of digestion, and all workers have agreed that there is no variation with meals. The observation of Elman and McCaughan (35) that in dogs with total external pancreatic fistulae there is no decrease in blood amylase demonstrates that any deficiency of this enzyme in the blood cannot be ascribed to lack of amylase absorption. That is, absorbed amylase plays no part in maintaining the blood amylase level.

#### SUMMARY

Normal human blood contains amylases, an esterase capable of splitting ethyl butyrate or tributyrin, a proteinase (or proteinases), phosphatase, catalase, and other enzymes of less clinical significance. There is present only a trace of lipase (capable of splitting olive oil); in most cases none is found. It is pointed out that many of the variable results described in the literature may be ascribed to variations in the methods used. It seems probable that there are at least two types of amylase, one which is most active in the initial hydrolysis of the starch molecule (liquefying amylase) and another which is more effective in producing the reducing sugars that are the end products of starch digestion (saccharogenic amylase). The esterase which splits ethyl butyrate or tributyrin has frequently been termed a "lipase"; it appears preferable to reserve lipase for the enzyme active on olive

TABLE III

| E 34 | 200 cc. saliva      | .3      | 10    | .2    | 10  | .2     | 10  | .2     | 10  | .2     | 11  |
| E 34 | 200 cc. juice       | .1      | 11    | .2    | 13  | .2     | 12  | .5     | 12  |        |     |

though in a few instances there are increases in the concentration of lipase or amylase which seem beyond the normal limits of variation. All analyses were made in duplicate by the methods previously used (22). From the evidence at hand, the absorption of minute

oil (or other triglycerides of the higher fatty acids). In acute pancreatic disease or experimental pancreatic obstruction the liquefying amylase of the blood is greatly increased; the data at present available on saccharogenic amylase show no change in this enzyme

under these conditions. At the same time blood lipase (olive oil) is also greatly increased but there is no change in the blood esterase (ethyl butyrate). In chronic pancreatic disease with failure of enzyme formation or after experimental pancreatotomy the liquefying amylase of the blood may be decreased, apparently without change in the saccharogenic amylase.

In liver disease or experimental liver injury the liquefying amylase of the blood is slightly increased in many instances. This increase is not sufficiently significant to be of clinical importance. It is reported that the saccharogenic amylase is decreased under these conditions. Clinical or experimental liver damage also results in a slight but significant increase in

serum lipase without any definite change in esterase. The serum phosphatase is also markedly elevated.

The changes in serum amylase (liquefying) are certainly of aid in the diagnosis of pancreatic disease. Further studies on lipase, phosphatase, and saccharogenic amylase may demonstrate the value of such determinations.

The possible origins of the increase in enzymes which follows liver injury is discussed.

Traces of enzymes are probably absorbed from the intestine into the blood stream. Such absorption is certainly insignificant and under normal conditions can have no effect upon the blood enzyme level.

## ABSTRACTS

STEINBERG, M. E., M.D., AND STARR, PAUL H., B.S.  
*The Factor of Spasm in the Etiology of Peptic Ulcers.*  
*Arch. Surg.*, Vol. 29, No. 6, Dec., 1934, pp. 895-907.

This article is an experimental study as carried out in dogs on the relation of spasm to the etiology of peptic ulcer.

In the first group of experiments, it was shown that where the jejunum was anastomosed to the pyloric valve and the alkaline content diverted away from the gastro-jejunal anastomosis, ulcers formed with regularity in each experiment. When the same procedure was used and three-fourths of the longitudinal and circular muscles removed for a distance along the jejunum, ulcers of the pylorus developed only occasionally. No ulcers were found in that part of the jejunum where the muscle layers had been denuded. In two of the ten animals studied, in addition to the ulcers of the pylorus, there were definite ulcers formed exactly where the muscles began their intact course, or about 10 cm. from the pyloric valve. Most experimental ulcers in the jejunum arise just below the pyloric valve.

In another series of six animals, the ileum was anastomosed to a Pavlov pouch and the muscle layers in the ileum stripped for a distance of about ten centimeters. No

ulcers developed in the denuded area and one of the six animals developed an ulcer in the area just distal to the denuded portion.

In a small series of animals undergoing the Exalto short-circuiting operation, exclusion of a large distal part of the stomach and also an entero-anastomosis opposite the gastro-enterostomy, none had ulcers. Without the entero-anastomosis, ulcers were produced in 75 to 100 per cent of cases.

The *modus operandi* in these experiments which prevented the ulceration in the denuded area of the small bowel, the authors feel is due to the release of spasm by means of stripping the muscular coat. They believe that a certain degree of acidity, depending on the particular area of intestine involved causes it to contract until the degree of acidity is reduced to a certain strength, but that ulcers will not be produced without the presence of certain other factors, among them, narrowing of the lumen due to spasm.

The authors feel that these observations support the neurogenic theory as an important factor in the etiology of ulcerations of the upper gastro-intestinal tract.

## SECTION III—Nutrition

### Insulin-Glucose Therapy in Heart Disease\*

By

E. STERLING NICHOL, M.D.  
MIAMI, FLORIDA

#### INSULIN—GLUCOSE THERAPY IN HEART DISEASE

**I**NSULIN-Glucose Therapy in heart disease has been extolled by many foreign physicians during the past eight years, but no very favorable report on the procedure has been issued in this country. In fact, recently, this use of insulin has been called worthless, unphysiological, and even dangerous by several American authors. My own experience with the use of insulin in more than one hundred cases of malnutrition during the past seven years drowned my fear of insulin in the non-diabetic patient, and led me to the trial of insulin-glucose therapy in various types of heart disease in patients who exhibited intact carbohydrate metabolism.

Briefly, we will review (a) the facts known about the rôle of insulin and glucose in the physiology of the heart muscle (b) the effects of insulin hypoglycemia on the circulation (c) some effects of insulin in non-diabetic subjects, and (d) clinical reports relating to the use of insulin-glucose in heart disorders. My own observations on a group of 20 patients with heart disease and treated with insulin in association with glucose orally, will be reported.

#### ROLE OF INSULIN—GLUCOSE IN THE PHYSIOLOGY OF THE HEART

It is more than thirty years since first it was shown that glucose is an essential source of cardiac energy. Since then, various researches (1) have established the following facts: The heart is exacting in its glucose requirements and uses up its own glycogen before drawing on available glucose. In addition to an adequate supply of glucose to maintain its work, however, the heart muscle requires an adequate supply of insulin, and of course oxygen. In the diabetic subject, there is failure of utilization of glucose by the heart muscle in a variable degree, but the ability of the heart to consume glucose is restored by insulin. In the normal subject, insulin increases glycogen storage when given in association with glucose, in all muscles and in the liver, but proportionately more in the heart muscle than it does in the skeletal muscles.

In the normal subject, the supply of glycogen in the heart muscle will not be lowered by exercise, provided an adequate supply of oxygen is available. However,

the heart muscle is less tolerant to deprivation of oxygen than is skeletal muscle, and is more sensitive to accumulation of lactic acid. It appears that the formation of glycogen from glucose under the influence of insulin favors the disappearance of lactic acid, thus aiding the recovery of muscle from exercise.

Ingested carbohydrate is absorbed very rapidly. The rise in blood sugar following the absorption of glucose supposedly stimulates the parasympathetic centers in the hypothalamic region of the brain, thus liberating insulin from the pancreas. Hence the beneficial effect noted clinically following the use of a high carbohydrate diet in heart failure may be due to the liberation of insulin in response to the rise in blood sugar, thus enhancing the power of the heart muscle to store glycogen.

#### EFFECT OF INSULIN HYPOGLYCEMIA ON THE CIRCULATION

If insulin is given freely without sufficient glucose, hypoglycemia results. The studies of insulin hypoglycemia effects on the circulation are not all in accord. (2) Increase in pulse rate is the general rule. In some subjects, both the systolic and diastolic blood pressure is lowered, while in others, the systolic level is sustained, or even elevated, and the diastolic level only is lowered. Apparently the decrease is least in the normal subject and greatest in diabetics with hypertension. Ernstene and Altschule (3) report, after study of insulin induced hypoglycemia in 16 normal subjects, an average increase of 29% in the circulatory minute volume, an increase of 73% in the pulse pressure, and an increase of 15% in the pulse rate, thus indicating that hypoglycemia is attended by an increased amount of cardiac work. These changes are similar to those following the use of epinephrine, and animal experimentation indicates that this effect results from stimulation of the sympathetic division of the autonomic nervous system. These signs disappear with the use of glucose in adequate amount.

Electrocardiographic studies during insulin hypoglycemia by various workers (4) have revealed reduction of the amplitude of R and T and in some cases even negativity of T waves, in diabetics with supposedly normal hearts. No clear-cut correlation has been established between the blood sugar level and the degree of change in the electrocardiogram. In patients with myocardial disease, extrasystoles, auricular fibrillation and other changes in rhythm have been demon-

\*Read before The American Therapeutic Society, Cleveland, Ohio, June 1934.  
Submitted December 6, 1934.

strated during insulin hypoglycemia. Middleton and Otway (5) reported three years ago, that after studying 11 diabetics with apparently normal hearts in insulin shock, the most marked change in the electrocardiogram was the flattening or inversion of the T wave.

It is generally agreed that, although the electrocardiographic alterations which appear during insulin shock do not immediately disappear following intravenous glucose injection, yet they are, in a general sense, transitory. Whether these changes are due to hypoglycemia, or due to a direct action of insulin on the myocardium, is not clear. Most continental authors favor the latter idea. Smith, (6) of London, points out that the electrocardiographic changes in *hypoglycemia* are quite similar to the changes to be found in *hyperglycemia*. He believes that in the diabetic, due to deprivation of insulin in the myocardium, there is deficient utilization of glucose, so that defective nutrition of the myocardium results. He assigns a subsidiary role to coronary disease in the diabetic, as far as the production of abnormalities in the electrocardiogram is concerned.

In the treatment of the diabetic with heart disease, occasionally it has been noted that insulin seems to produce angina, and even coronary thrombosis (Parsonnet and Hyman.) (7) In addition, congestive failure may be induced or accelerated through the use of insulin in diabetics with myocardial disease. It is established that anoxemia of the myocardium will give rise to anginal pain; it seems apparent that too extreme a reduction of the glucose supply to the myocardium also will produce anginal pain. Hence it is all the more likely, according to Smith (6), that these two physiological aberrations might cause very similar electrocardiographic changes.

#### SOME EFFECTS OF INSULIN IN NON-DIABETIC SUBJECTS

In more than half of non-diabetic patients with *malnutrition* treated with insulin and high carbohydrate diet, a substantial gain in weight and strength is produced (8). The increase in weight may be due, in part, to the improved appetite following the use of insulin, but it is in part due to the better assimilation of food. It has been noted by almost every physician reporting on the use of insulin in non-diabetic subjects, that insulin exerts a marked tonic effect, in that it increases the feeling of well being in the patient so remarkably.

It has been shown by Boldyreff and Stewart (9), as well as others, that insulin has a secretagogue effect on the gastric glands. Okada (10), *et al* showed that in addition insulin provoked pancreatic and biliary secretions. Leuders and Watson (11) showed that insulin increased the pancreatic ferments in their group of underweight patients under treatment, and improved the character of the biliary secretions in some. Gage (12), *et al* recently have shown that insulin increases intestinal activity. Both experimentally and clinically then, it has been amply shown that insulin improves the function of the entire digestive tract.

Blotner (13) has found, when insulin is used in similar patients, an increase in plasma protein concentration as well as moderate increase in the red blood cells. The same author recently has shown that in some non-diabetic patients there is a slight increase in sugar tolerance following insulin therapy, but con-

cluded the finding was of no practical importance since the tolerance invariably returned to normal later.

#### CLINICAL REPORTS RELATING TO THE USE OF INSULIN-GLUCOSE IN HEART DISORDERS

In 1926 Osato (14) reported one patient with heart failure as being greatly improved by the use of insulin and glucose intravenously. Since then many favorable clinical reports have appeared in the literature concerning insulin-glucose therapy in heart disease.

Rimbaud (15) *et al* used 5 to 10 units of insulin daily or twice daily, with 50 to 100 gms. of dextrose orally, and obtained relief from anginal pain and dyspnoea in their patients. Bickel (16) used from 10 to 30 units of insulin daily, with 100 to 200 gms of dextrose orally or half this amount intravenously. Kisthinos and Gomez (17) claimed good results in patients with heart failure with the use of 4 units of insulin followed by 80 gms of glucose orally for a ten day period.

Jorge and Sobrinhe (18) noted improvement in 10 cases of congestive heart failure, due particularly to right ventricle insufficiency, as evidenced by lessened dyspnoea, diuresis, and lowering of increased venous pressure. They showed electrocardiograms of five patients so treated, demonstrating improved rhythm and in some cases improved amplitude in the ventricular waves. Wiener (19) proclaimed good results but did not state the number of patients treated. Carriere and Hurtz (20) reported in detail their results in 47 patients, using 200 cc of 30% dextrose (60 gms) intravenously, followed by 5 or 10 units of insulin, for a period of ten days. They noted improvement in dyspnoea and precordial distress, slowing of rapid rates, lowering of arterial tension and diuresis in some. In 13 cases, due to exophthalmic goitre, they noted slowing of the pulse rate and disappearance of extrasystoles. Their best results were in patients with congestive heart failure (right ventricle failure) and their poorest results in left ventricle failure without edema. Electrocardiographic studies in some instances showed amelioration of rhythm, disappearance of extrasystoles, but deformities of the ventricular complexes were not influenced by the insulin-glucose therapy. Mathieu, Colleson, and Simonin, (20-a) found favorable changes in the electrocardiograms of ten patients treated with insulin and glucose over a period of one to three weeks. Increased amplitude of R was noted in all, and in two, a flat T became upright.

Amaral (2) reported favorable improvement among 22 patients with heart failure due to valvular lesions, or myocardosis or right failure due to chronic pulmonary disease. He used daily, for ten days, four units of insulin followed by 80 gms of glucose orally.

Lopez-Brenes (22) advocate the use of insulin-glucose in selected cases of myocardial degeneration with coronary sclerosis. They noted in some patients with subjective symptoms without congestive failure, favorable changes in the electrocardiogram, such as disappearance of arborization block.

Sprague and Camp (23) reported in 1932 their results with intravenous glucose without insulin in 12 cases of congestive failure, 3 cases of coronary thrombosis and 4 cases of paroxysmal dyspnoea. The last group only obtained benefit.

Olascoaga (24) states that in 20 patients with cardiac insufficiency of varied etiology, insulin-glucose therapy proved effective even when usual methods

failed. He noted slowing of the pulse rate, improvement in dyspnoea, and disappearance of gallop rhythm and signs of congestive failure. He also depicted with orthodiagrams reduction in size of dilated heart chambers. He found an increase in systolic pressure decrease in diastolic pressure, increase in the oscillographic index, all of which, he felt indicated an improved cardiac tone. If fibrillation of the auricles existed, the results were not so striking.

Recently, Smith and Lutén (25) reported their results with intravenous glucose in 16 patients with advanced congestive failure. They concluded such therapy was indicated as an emergency only where digitalis failed to restore compensation and denied insulin any credit. In view of the fact that analysis of their cases reveals that only one patient received more than three injections of glucose, while 6 received only one injection, it hardly seems worth while judging the efficacy of glucose therapy used so sparingly in the face of a chronic disease process. Furthermore, since they used insulin in only 5 patients, in dosage of 5 units one to three times and 10 units once, it seems obvious that their opportunity to be impressed with the advantages of insulin was meager.

Last year Smith (26), of London, reported quite favorably on the use of insulin-glucose in 40 patients with the anginal syndrome, subject to frequent attacks and preceded by routine therapy without avail. His method consisted of 5 units of insulin twice daily, followed by a meal including 30 gms of glucose, over a period of 2 to 17 weeks.

White (27) in his recent treatise on heart disease makes no mention of the use of insulin and scant reference is made to the use of glucose intravenously. Hyman and Parsonnet (28) in their recent monograph, speaking of therapy in coronary thrombosis recommend highly intravenous glucose in the second and third stages of the coronary attack, but warn against the use of insulin in diabetics, unless the diabetes is severe.

### INSULIN-GLUCOSE THERAPY IN TWENTY CASES OF HEART DISEASE

This report summarizes my observations on a group of twenty patients with heart disease treated with insulin in association with a high carbohydrate diet, and extra feedings of glucose. The series comprises 13 private cases and 7 from wards of Jackson Memorial Hospital. There were 13 men and 7 women, ranging in ages from 27 to 83 years.

#### METHOD

Patients who received glucose *intravenously*, in association with insulin, were not included in this study. In every instance other drugs either were discontinued, or the patient had a control period of a number of weeks in which to reach a stationary point, before the initial use of insulin-glucose, in order to properly evaluate the insulin-glucose effect. If the patient was in the hospital the nurse was instructed to give five units of insulin fifteen minutes before meals. The diet included abundant carbohydrates, and extra feedings of 30 gms of glucose in fruit juice were given two hours after each meal. If the patient was ambulatory or home under the care of a nurse, he or some responsible member of the household was instructed in the use of insulin. In the event of improvement, the dose of insulin usually was not increased, but if no improvement was noted after a few days, and no intoler-

ance for insulin observed, the dose was then doubled.

Instead of the smaller doses usually advocated, my experience indicates that 15 to 30 units of insulin daily is required to produce maximum benefit. If intolerance for insulin developed, as indicated by nervousness, palpitation, anorexia or nausea, the insulin was discontinued for a few days. If the signs of intolerance developed again on resuming insulin, the method was considered a failure for that patient. The duration of treatment varied from two to eight weeks except in some cases of intolerance.

#### TYPES OF CASE AND RESULTS NOTED

(1) Five patients had suffered previous coronary thrombosis. One had developed congestive failure, and no improvement was noted with insulin-glucose, and she died later. The other four were having angina of effort, or showed signs of left ventricular failure. All of these improved with insulin-glucose, as indicated by lessened dyspnoea, increased strength, or improved tolerance for exercise without angina. The improved spirit in one case was very striking.

This case, Dr. D., was an active surgeon, 48 years of age, who had suffered a coronary thrombosis in April, 1933. On arrival in Miami in January of this year, he could not walk more than a few yards without anginal pain, and was markedly depressed in spirits. By April, he could walk a hundred yards without pain, but the mental state was not much improved. The weight was 122 pounds, fasting blood sugar was 93 mgs. blood pressure was 110/80, examination and electrocardiogram showed nothing remarkable. Insulin was then started, his optimal dose being 30 units daily. He gained ten pounds in weight, felt stronger, tolerance for exercise mounted rapidly, and the effect on the depression was nothing short of remarkable, and I am convinced it was not psychic.

One of these cases used insulin-glucose therapy on several occasions with benefit each time.

C. F., a man of 72 years, has been under observation the past six years. At first he showed only general arteriosclerosis and biliary insufficiency, and insulin was used as a tonic and to induce weight. About two years ago he developed moderate essential hypertension and anginal pain. A year ago he had a coronary thrombosis, for which he was in bed two months. Following this, he developed dyspnoea on exertion, and angina of effort. Insulin was used on three different occasions and each time he improved in strength, and both dyspnoea and anginal pain were ameliorated, and digestion improved. His improved feeling of well-being was notable.

(2) Four patients had coronary sclerosis, combined with hypertension and showed signs of left ventricle failure. One of these, a man of 55, was intolerant to insulin and treatment of usual type was continued. The other three improved moderately, with lessened dyspnoea, slowing of the pulse rate, and increased strength. (The further progress of one was hindered by the onset of pleurisy, after insulin had been used two weeks, but up to that point, improvement was notable.)

(3) Three patients had coronary sclerosis and left ventricle failure, but their clinical picture was overshadowed by a severe chronic nephritis. Temporary amelioration of dyspnoea was noted in these cases, but their disease process soon caused their deaths.

(4) Three patients suffered from angina of effort, and showed evidence of coronary sclerosis without cardiac hypertrophy. All derived definite benefit from insulin-glucose therapy, but did not lose their anginal syndrome completely. One, a man of 83 years, had first been diagnosed angina pectoris 26 years

previously. He was found to have auricular fibrillation also. His clinical picture was clouded, due to a distressful diverticulosis of the colon, and intermittent claudication. His improvement was as much due to his better digestion, probably, as to the effect on the myocardium itself. Another patient, a man of only 34 years, had been told he had a coronary thrombosis, but careful inquiry revealed only a probable coronary sclerosis. There was an element of mild hyperthyroidism in this case, and very likely some severe seizures of precordial pain he developed were of psychogenic origin. At any rate, he gained 27 pounds in six weeks, with the use of insulin-glucose therapy, and made a striking general improvement, and for several months his pains were greatly ameliorated, though since his return north the seizures are intolerable again.

(5) Three patients had mitral stenosis, due to rheumatic heart disease. Two of these were intolerant to insulin (one with tachycardia without congestive failure, and one with marked congestive failure.)

S. M., the patient of this type who did improve, was a man 37 years of age, who gave a history of rheumatic disease in childhood and presented signs of mitral stenosis. There was no evidence of congestive failure, but tachycardia was bothersome, and he was weak and asthenic, his fatigue keeping him abed a great deal of the time. Some foci of infection were eradicated, without any pronounced improvement in his health. He was then given insulin-glucose therapy, with good results. The weight increased 15 pounds, there was much less palpitation, he became stronger and though his progress was interrupted at one time with a severe respiratory infection, he eventually after an aggregate of two months of insulin-glucose therapy, was able to resume his work. He has since maintained his improvement.

(6) Two patients were diagnosed as cardio-neurosis. One of these cases had essential hypertension, and improved in her general feeling of well being and strength. The other showed no improvement after a month's trial with insulin and glucose treatment.

In summary, then, ten, or 50% of the cases showed improvement under treatment with insulin and glucose.

#### ELECTROCARDIOGRAPHIC CHANGES

Electrocardiograms were obtained before insulin-glucose therapy was started in all cases, and repeated at the end of the therapy with some exceptions. In no instance was there any electrocardiographic evidence suggesting that the use of insulin in this fashion had produced unfavorable changes in the myocardium. On the other hand, slowing of rate, disappearance of extrasystoles, increased amplitude of R or elevation of T, was demonstrated in five out of the ten cases who improved with insulin-glucose treatment. This suggests that a beneficial change in the nutrition of the myocardium had been brought about in these cases.

In case O. M., a definite change from negative to upright T-2 occurred, but as this patient had received twelve grains of digitalis during 48 hours prior to the initial electrocardiogram, it is possible that the negative T-2 was in part digitalis effect. In this same case, T-3 had been negative, with high take off, and became isoelectric. Digitalis was withdrawn, and insulin used for only two weeks, then the second electrocardiogram was obtained.

In case C. F., negative T-2 became isoelectric, but in this case insulin was being used for the third time five months after the first electrocardiogram was ob-

tained. It is of course possible the change in T-2 may have occurred in this length of time without benefit of insulin therapy, but even if in each case some reason could be ferreted out to which favorable change might be ascribed other than insulin, the absence of deleterious effect in the electrocardiogram remains significant, and makes one less fearful of such use of insulin.

#### COMMENT

Parkinson (29) has recently reminded us that too much attention has recently been centered on the anginal death, and too little on the anginal life and its management. This applies equally well to most cardiac states, so if insulin-glucose therapy will improve patients with heart disease, and can be used safely, it is worth finding out.

In the many reports in the literature relating to insulin-glucose therapy in non-diabetics, no anginal episodes were recorded, in spite of the occasional report of coronary symptoms following the use of insulin. The fear of insulin reaction in the diabetic with heart disease is justifiable, but in the non-diabetic, partaking of a liberal amount of carbohydrate and extra feeding of glucose, the chance of insulin-hypoglycemia is slim indeed. Those patients I have observed who were intolerant to insulin-glucose therapy, gave notice of their intolerance by palpitation, nervousness, anorexia, and nausea, but not by cardiac pain or collapse. That insulin therapy of this sort may be used with impunity is further borne out in the group studied here, by the absence of unfavorable electrocardiographic changes following the procedure.

If hypoglycemia in the non-diabetic commonly causes cardiac pain, this should be a prominent symptom in the reported cases of hyperinsulinism. But such is not the case, in fact in the symptom complex of 65 cases recently collected from the literature by Tedstrom (30) only one patient had attacks of typical coronary disease. The electrocardiograms on this patient reverted to normal, however, on elevation of the sugar level.

In the diabetic patient, using insulin, the glucose in the diet is calculated to just meet the insulin requirements, so that hypoglycemia is not uncommon. However, in the non-diabetic, such close calculation of diet is not necessary, and an excess of glucose can be given, and should be given, thus avoiding hypoglycemia with its attendant dangers for the cardiac patient, but the "tonic" effect of insulin on the heart is produced, nevertheless.

It is necessary to keep in mind that insulin, (in addition to glucose and oxygen) is required by the heart muscle to do its work. As pointed out above, insulin increases the ability of the heart muscle to utilize glucose, and this effect is directly on the heart muscle, and is not to be confused with the effect of insulin hypoglycemia on the circulation.

Smith (26) is of the opinion that insulin also aids the resolution of early atheromatous changes in the coronary arteries, through promotion of the combustion of fat. He also suggests that the improved nutrition in the myocardium resulting from the use of insulin prevents the accumulation of substances capable of producing anginal pain. In my opinion, although neither of these conceptions can be proved, they have a logical basis on the physiological facts noted above.

Fig. 1. Case O. M.: Biphasic T-2. Before insulin (A). After insulin-glucose therapy (B). T becomes upright.

Many patients with anginal syndrome have associated gall bladder disease, or other disorders of the digestive tract, which frequently seem to incite the anginal pain. In view of the well established fact that insulin improves the biliary, gastric and pancreatic secretions, it is quite likely that the lessened anginal attacks in some patients, following insulin-glucose therapy, are due to improved digestion. This holds for other types of heart disease also, for the

Fig. 3. Case W. A.: Flattened T in all leads and low voltage of QRS before insulin (A). Improved character of T in all leads, increased height of QRS in lead I, with shift to left axis deviation, after insulin-glucose therapy.

flatulence and general abdominal discomfort of many heart patients, particularly those with congestive failure, are important contributing factors hindering their progress, and any improvement in the digestion is a distinct gain to the patient.

I should like to stress the difference between using glucose in the diet, coupled with insulin, as I have done in the 26 cases reported here, and the use of glucose intravenously in hypertonic solutions with in-

Fig. 2. Case C. F.: Negative T-2 and low voltage of QRS before insulin (A). Isoelectric T-2 and increased height of QRS after insulin-glucose therapy (B).

sulin. The latter method is cumbersome, entails hospitalization, is not without danger, and frequently has to be abandoned because of sclerosis of the veins, and can never be continued many days. On the other hand, by including an ample supply of carbohydrate on the diet, and extra feedings of glucose, insulin-glucose therapy may be continued over as long a time as desired. For example, two patients in this group took insulin for two months. Since insulin improves the

Fig. 4. Case C. K.: T-1 isoelectric, premature contractions present before insulin (A). Decreased height of R but absence of premature contractions after insulin-glucose therapy (B).

digestion, rarely was any complaint registered about the amount of sweet fruit juices necessarily imbibed. There is scant need of using glucose intravenously instead of in the dietary, in the treatment of heart disease, except as an emergency measure in advanced cardiac congestive failure, or in combating shock after coronary thrombosis, or in circulatory shock from other sources.

Probably one of the most important uses of insulin-

glucose therapy will prove to be in the patient with moderate coronary artery disease, without advanced congestive failure. How many patients with myocardial infarction go moping along after their period of acute illness is over, from one to three years, almost afraid to live, their chief preoccupation being the struggle with insurance adjusters! They far too frequently become introverts and arrive at various stages of chronic depression of the spirit. For them, treatment with insulin-glucose serves a double purpose in that it not only improves the actual nutrition state of the myocardium, but through its tonic effect buoys up the spirit remarkably. And, if by chance they are underweight also, the induced gain in weight has an excellent psychic effect, which may even be reflected from the jovial remarks of their friends.

### SUMMARY AND CONCLUSIONS

The use of insulin, in association with glucose, is not empiric treatment in heart disease, but is based upon physiological evidence that this procedure improves the nutrition of the myocardium.

A review of the numerous published clinical reports

indicates that insulin-glucose therapy has a beneficial effect on various types of heart disease, in spite of the obvious difficulty of assessing the value of any specified treatment in cardiac patients.

In a group of 20 patients with heart disease, 50% improved with the use of insulin in association with a high carbohydrate diet and extra feedings of glucose. Patients with the anginal syndrome or coronary thrombosis, with or without left ventricular failure, are in particular likely to derive benefit from such therapy.

It is not proposed to use insulin-glucose therapy in place of other routine measures, but more as an adjunct to other methods of treatment.

Electrocardiographic studies indicate that no untoward effects are obtained following the use of insulin-glucose in the non-diabetic subject with heart disease, and evidence of improvement in the nutritional state of the myocardium is obtained in some cases.

The benefit derived in cardiac patients is due not only to improved nutrition of the myocardium, but may be due in part to improved digestive functions and elevation of the general spirit of the patient.

# Acid-Base Value and Assimilability of Fruit Juices\*

By

I. NEWTON KUGELMASS, M.D.†  
NEW YORK CITY, NEW YORK

FRUIT juices constitute an essential source of readily available nutrients for sick children. The juices replenish rather rapidly the three body constituents, water, salts and dextrose whose loss even in a small measure markedly affects the regulatory processes of the body. The purpose of the present study is to determine the acid-base values of fruit juices, the gastric response to their ingestion and the degree of availability of their constituents.

## METHODS

The hydrogen ion concentration was determined colorimetrically by solutions standardized potentiometrically. The same fruit juice solutions were used for the determination of total titrable acidity. 100 cc. of some of the fruit juices were offered to convalescing young children as a test meal and the gastric juice obtained by tube at the end of 15 and 30 minutes respectively for their *pH* determinations. Membrane equilibria were studied with 30 cc. of each fruit juice dialyzed in a collodian membrane and suspended in a beaker containing an equal volume of 1% saline solution. The refractive index, the *pH*, the sugar content, the phosphate and the total base all were determined before and after an hour's dialysis for the evaluation of the degree of availability of these constituents.

The *pH* determinations of the fresh fruit juices show that lemon juice has the highest acidity of all fruits, *pH* 2. Orange, grape and pineapple juices have a *pH* value which ranges about 3; tomato, apple and banana juice fluctuate about *pH* 4; beet juice appears on the alkaline side at about *pH* 9. The total titrable acidity parallels the *pH* level of the fruit juices, i.e., the higher the acidity the greater the titration value to *pH* 9. The fruit juices fluctuating about *pH* 3 stimulated with the first 15 minutes after ingestion a gastric *pH* of about 3.5. Fruit juices fluctuating at about *pH* 4 stimulate after a longer period a gastric *pH* of about 4.5. The gastric value obtained upon ingestion of fruit juices apparently depends upon the associated content of the food acid contained—citric in lemon, mallic in apple and the combination of both in tomato. (Table I).

A titration curve of any of the fruit juices reveals that they are mixtures of weak acids and their salts containing relatively small amounts of free acids. Lemon juice, for example, is an acid buffer salt mixture containing about 10% free citric acid, 60% of the primary citrate, 20% of the secondary citrate and about 2% of the tertiary salt. The sugar present in the fruit juices tends to decrease the *pH* value but exerts no buffer value except on the extreme alkaline range beyond biological significance.

These acid-base studies have thus shown fruit juices to be buffer solutions containing sugar. They are rather desirable for administration in the course of acute illness because of the nature of their composition. The question that arises is readiness of the availability of the salts and sugar upon ingestion. A first approach to this problem has been made by setting up a series of semi-permeable membrane experiments with fruit juices in a dialyzing sac and physiologic saline surrounding it. Such an analysis of

TABLE I  
Fruit and Gastric Juice Values

|           | Fruit Juice |                            | Gastric   |
|-----------|-------------|----------------------------|-----------|
|           | <i>pH</i>   | Titrable (H <sup>+</sup> ) | <i>pH</i> |
| Lemon     | 2.2         | 3.9                        | 3.1       |
| Orange    | 3.0         | 1.0                        | 3.6       |
| Grape     | 3.2         |                            | 3.3       |
| Pineapple | 3.4         | 1.0                        | 3.0       |
| Tomato    | 4.2         | 0.5                        | 4.5       |
| Apple     | 4.3         | 0.5                        | 4.8       |
| Banana    | 4.6         | 0.2                        | 4.6       |
| Beet      | 5.8         |                            |           |

relatively simple membrane equilibria *in vitro* is in a physico-chemical sense comparable with the primary conditions which maintain in the upper alimentary tract.

The results given in Table II show that the *pH* before and after equilibrium attainment remains relatively constant in spite of changes in the concentration of the constituents. The refractive index shows the degree of dilution that takes place in the course of exchange. Sugar as a non-electrolyte is the substance that rapidly permeated the membrane. But the basic constituents, the acid or electro-negative ions pass less rapidly than sugar and the basic or electro-positive ions remain more or less intact. In fact, the total base of the fruit juices has been observed to increase in content resulting from the shift of the sodium ion from the dialyzate. While this was at first in discord with the accepted notion of the ready availability of the basic salts in fruit juices, the observation is however in accord with Donnan's theory of membrane equilibria. The inference is that basic salt constituents are the last to be absorbed from such solutions.

The increased basic salt content observed in the distribution of substance on each side of a membrane is due to the presence of a fruit protein, the molecules and anions of which cannot pass through the membrane early in course of digestion. The mechanism of

| C <sub>1</sub>  | C <sub>1</sub> | C <sub>2</sub>  | C <sub>2</sub>   |
| I               |                | II              |                  |

#### Equilibrium State

|                     |                |                  |                     |                     |
|---------------------|----------------|------------------|---------------------|---------------------|
| Na <sup>+</sup>     | R—             | C <sub>1</sub> — | Na <sup>+</sup>     | C <sub>1</sub> —    |
| (C <sub>1</sub> —X) | C <sub>1</sub> | X                | (C <sub>2</sub> —X) | (C <sub>2</sub> —X) |
| I                   |                |                  | II                  |                     |

This is the nature of things observed in the dialyses of the fruit juices which has definite bearing upon assimilability of the fruit juice constituents by the living membranes of the alimentary tract.

#### CONCLUSIONS

1. Fruit juices are buffer salt solutions whose utilization is favored by their acidity.
2. The dissolved sugar in fruit juices is the most readily absorbed constituent.
3. The fruit juices whose pH ranges at about 3—lemon, orange, grape and pineapple create a higher gastric content than those whose pH range fluctuates at about 4—tomato, banana.
4. The base-forming constituents of fruit juices are the slowest to be absorbed by virtue of the existent Donnan membrane equilibria.

## A New Concept of Meniere's Disease and its Response to Antiretentional Therapy

By

EUGENE FOLDES, M.D.\*  
NEW YORK CITY, NEW YORK

**R**ETENTION of water, salt and other mineral substances in one organ or another, frequently is productive of disease. The diseases developed in this manner are usually classified under various headings. Thus, temporary intracranial accumulation of liquids appears to play a most significant role in the patho-

genesis of epilepsy and migraine, customarily grouped with the diseases of the nervous system. Similarly, eclampsia of pregnancy, attributed to toxemia of pregnancy, would seem rather to be due to temporary intracranial accumulation of liquids. The same factor appears to be pathogenically important in eclampsia of infancy, frequently brought into relationship with spasmophilia. Aside from the brain, temporary liquid retention also may occur in other organs. Under certain conditions angina pectoris ("coronary disease") may develop if temporary accumulation of liquids

\*All the foregoing considerations have been made the subject matter of a monograph (Foldes, A New Approach to Dietetic Therapy, etc. Metabolism of Water and Minerals and its Disturbances, Richard G. Badger, Boston, 1933) to which I refer for detailed description and bibliography.

\*Formerly Assistant Professor of Medicine, Univ. of Budapest, Hungary. Submitted February 9, 1935.

takes place within the pericardium, bronchial asthma ("disease of the lungs") if it develops in the lungs, gout ("disturbance of the uric acid metabolism") if in the joints, allergic diseases if in the mucous membranes of the respiratory organs, of the gastrointestinal tract, or in the skin, etc. All these diseases manifest themselves in the form of attacks of one kind or another, and in all of them the accumulation of liquids is temporary in the organ of pathogenic significance and occurs simultaneously with the paroxysm. The elimination of such temporary retentions would seem to bring the attack to an end. Attention is called to the fact that although all these attacks seem to be directly due to a liquid accumulation which is local in its extent, nevertheless in all conditions enumerated there is also a generalized liquid retention present throughout the organism. In other conditions the generalized retention of liquids in itself, which is permanent rather than temporary and has no local predilection, appears to be pathogenically significant, as for instance in hypertension, pernicious anemia, etc.†

With reference to the diseases characterized by paroxysms and caused (in addition to other factors) by a temporary and local retention of water and minerals, I have called attention to the fact the *Menière's disease* (the term preferred by otolaryngologists is *Menière's syndrome*) seems to belong with this group. Thus, according to Wittmarck (2), *Menière's disease*, consisting of sudden paroxysms of dizziness which are associated with nausea, vomiting and unilateral deafness and tinnitus, is due to the sudden increase of the endolabyrinthial pressure caused by temporary accumulation of liquids within the labyrinth. Wittmarck assumes that the disturbances in the function of the vestibular apparatus are caused by a paralysis of the terminal parts of the sensory nerve and organ due to the increased pressure. In favor of this assumption he calls attention to the fact that after the attack, the disturbance in function disappears to a great extent. In severe cases, degenerative changes of an irreparable character develop as a consequence of hydrops. Further, Dederding (3) finds that there is a relationship between the water and mineral metabolism and *Menière's disease*, inasmuch as there is a relapse following water retention and an improvement after increased diuresis produced by the administration of salyrgan. This author assumes that *Menière's disease* develops on the basis of an edema of the labyrinth.

Accordingly, there seems to be a striking similarity in the pathogenesis of *Menière's disease* on the one hand, and on the other of epilepsy, eclampsia of pregnancy, eclampsia of infancy, migraine, angina pectoris, bronchial asthma, the allergic diseases and gout. All these diseases manifest themselves in the form of attacks which appear to be due to a retention of water and minerals that is (1) local and (2) temporary, rather than generalized and continuous. Also, in all of these diseases, the attacks cease when the retained liquids disappear from the respective organ. The fact that notwithstanding these similarities, the affections enumerated appear to be so widely different that most of them were grouped with the diseases of the various organs rather than with the disturbances of the water and mineral metabolism, is attributable to the difference in the location of the liquid retention, inasmuch as it occurs in one or the other of the various organs.

The characteristics of the organ entering the clinical picture and modifying it to a great extent, and the lack of recognition of the underlying factor of the disturbed water and mineral metabolism in every instance, explain why the analogies escaped attention for a long time.

For the treatment of the group of diseases under discussion an antiretentional therapy has been developed. This therapy is based on the consideration that if retention of liquids plays such a significant—*sine qua non*—rôle in pathogenesis as has been assumed, elimination of retained liquids and prevention of subsequent development of retentions should prevent the occurrence of the paroxysms enumerated. For this purpose, the antiretentional therapy employs a diet, based on the recognition of the fact that all food elements, such as proteins, carbohydrates, fats, water, minerals and vitamins influence the water and mineral metabolism in one direction or the other, i.e. leading either to retention or increased diuresis. Restricting the amount of food elements in the diet which are retentive and utilizing in a liberal measure those of antiretentional properties, the antiretentional diet is built in the following manner.

*Proteins* (antiretentional) are administered in liberal amounts, 1.5 to 1.8 grams per kilogram ideal weight, daily.

*Carbohydrates* (retentive) are restricted to 2.5 to 3.5 grams per kilogram ideal weight daily in the initial stages of the therapy and later increased to the extent which is necessary to maintain the body weight.

*Fats* (retentive) are restricted to from 40 to 50 grams daily.

*Minerals*: Excess in the ingestion of salt (retentive) is to be avoided (in certain cases an unsalted—not salt-free—diet is administered). Other mineral substances are to be employed only as represented in the various food substances.

*Liquids* (frequently retentive) are restricted to from 1.0 to 1.5 liters daily including the liquid content of fruits.

*Vitamins* (mostly antiretentional) are freely utilized but only in their natural state (concentrated preparations are given only in case of special indication, and only occasionally and in small amounts).

The antiretentional diet has been put to a test in such conditions as were attributed to liquid retention, local and temporary, as well as generalized and continuous. The results were gratifying in most instances. In view of the fact that the pathogenesis of *Menière's disease*—with reference to which no therapeutic attempts have been described in the previous publication because no suitable cases were encountered before the work was closed—seems to be essentially similar to that of the other diseases in this group, and differs only as to the location of liquid retention, it was proper to examine the effects of the new therapy upon it.

I found that while the antiretentional diet in itself, or together with the administration of phenobarbital, is ineffective, the addition of quinine sulphate, phenobarbital and the extract of *nux vomica* to an antiretentional diet, the protein content of which is slightly lowered (to approximately 1 gr. of protein per kilogram ideal weight daily) is followed by a complete

disappearance of the attacks within a few days, with no relapses observed thus far.

*The diet administered was as follows:*

*Breakfast:* 180 cc. orange juice, from 30 to 60 grams of bread, one square of butter, one cup of coffee (caffeine extracted), one tablespoonful of cream, one teaspoonful of sugar.

*Lunch:* 30 grams of cheese, or two eggs, raw vegetables such as lettuce and tomatoes, 30 to 60 grams of bread, 150 to 180 grams of raw fruits.

*Dinner:* 120 to 150 grams of meats, calf's liver, chicken or fish, vegetables (using those, the carbohydrate content of which does not exceed 17 per cent,) 30 to 60 grams of bread, 150 to 180 grams of raw fruits.

Over twenty-four hours. 4 glasses of water.

*The medication administered was the following:*

Quinine sulphate 0.25 gm.

Phenobarbital 0.02 gm.

Extractum nucis vomicae 0.01 gm.

This was given three times a day for two weeks, then twice the day following, once the next day and, after an interval of three days, the same medication was repeated in a similar manner for the same period. Subsequently the diet as well as the medication was discontinued.

#### CASE REPORTS

1.—*Mr. J. D., age 43.* One niece is suffering from headaches, no other family history. Complains of terrific dizzy spells. Fatigued in the morning of the day of the attacks, in addition to which later belching, heaviness in the stomach and headaches on both sides of the forehead develop until he is seized by sudden dizziness, nausea and usually vomiting. The attacks last several hours, during which time he has to maintain a reclining position. The first such paroxysm occurred fifteen years ago, the second, ten years ago, during the last two years they developed at irregular intervals from once weekly to once in two or three months, while during the last two months they occur on the average of once a week. For the past eight years he has eschewed meats and taken ten glasses of water daily. All previous examinations gave negative results and all forms of treatment were ineffective.

The examinations showed a deafness of the right ear, lateral nystagmus and bradycardia (pulse rate 56), but no other changes.

After the beginning of the therapy (September 6, 1932) the dizzy attacks did not again recur. In the first few days, occasional headaches of short duration and heaviness in the head manifested themselves, but subsequently even these disappeared. Four days following the discontinuance of the therapy, the patient experienced an attack of headache, vomiting and perspiration without dizziness, but since has enjoyed complete freedom from attacks to date (January, 1935).

2.—*Mrs. I. M., age 46.* Ten years ago tinnitus of the left ear for more than a year. Tinnitus of the same ear six years ago for a month. For the past two months severe spells of dizziness almost daily forcing her to maintain a reclining position. Dizziness also on moving the head and on changing position.

The examinations showed deficient hearing bilaterally, but no other changes.

On the first day of the therapy (February 28, 1933) the patient had an extremely severe attack of headache with polyuria, but the dizzy spells disappeared within a few days and have not recurred to date (January, 1935). Dizziness was experienced only on changing position for a few weeks after the beginning of the therapy and occasionally thereafter.

3.—*Miss I. M., age 46.* For the past four weeks, two or

three times weekly spells of dizziness, ringing in the right ear and nausea, forcing her to lie down.

Except for defective hearing of the right ear, the examinations were negative.

On the second day of the therapy (September 12, 1933), a very severe attack of dizziness occurred after which the symptoms did not recur (last heard from June, 1934).

4.—*Mr. S. S., age 38.* For the past four years ringing in the right ear. For the past two years attacks of severe dizziness for about two hours, followed by vomiting from seven to eight hours. Before the attacks there is a gradual increase of the tinnitus, and following them a decrease. Feels weak and has no appetite for a day or two after the paroxysms. These formerly occurred once in three to four months, for the past three months, however, twice weekly. All previous examinations revealed normal conditions aside from a unilateral impaired hearing, and patient was discharged with the explanation that no effective therapy existed (New York Hospital).

The examination showed a defective hearing of the right ear, but otherwise conditions were essentially normal.

Following the beginning of the therapy (September 7, 1934) a polyuria developed on the second and third day and a mild headache on the fourth day; felt dizzy and had aura several times for a few minutes. Yet, the dizzy spells and vomiting did not recur (last information May 1, 1935).

#### COMMENT

In an attempt to analyze the mechanism of the effect of the therapy outlined, attention is called to the fact that the antiretentional diet, either by itself or in combination with the administration of phenobarbital, was ineffective. On the other hand such a complete abolition of the attacks as has been observed in these four cases can hardly be ascribed to the medication in itself. I shall endeavor to show that the therapeutic results might be explained assuming a concerted action of the diet and medication.

As to one constituent of the mixture consisting of quinine sulphate, phenobarbital and extract of nux vomica, phenobarbital was found to be ineffective in a case (Mr. J. D.) in which the addition of the other two constituents, in combination with the diet, led to a cessation of the paroxysms. Nevertheless phenobarbital was retained for the reason that it apparently has a stabilizing effect on the water metabolism which in Menière's disease seems to be disturbed. It has been pointed out, that phenobarbital has diuretic effects in certain instances of liquid retention, and in other instances is capable of preventing sudden mobilization. I have called attention to the fact that in that group of diseases to which Menière's disease also belongs, both retention and mobilization of liquids are undesirable from a therapeutic point of view.

Further, it is not likely that the administration of the extract of nux vomica by itself could have produced the improvement in the cases described. Yet it was included in the mixture for its well known tonic effect on the nervous system, with the hope that the vestibular nerve might thus be influenced.

Although conclusive evidence is yet to be obtained, it may be assumed that the really potent factor of the mixture is quinine sulphate which, according to some observers, occasionally brings relief from the horrors of Menière's disease. The fact that the great majority of investigators could not confirm the favorable results, however, and that for this reason it is but rarely employed today, demonstrates sufficiently that the results observed in the four cases previously described are not attributable to the administration of quinine

sulphate by itself, but to the concerted action of quinine sulphate and the diet. Such concerted action might be assumed for the following reasons.

Menière's disease may be recognized as apparently a member of the group of pathological conditions caused by temporary local liquid retention. Consequently the absence of therapeutic response of Menière's disease to the antiretentional diet which has shown its effectiveness in a considerable number of various cases, had to be attributed to an unusually firm fixation of liquids in the organism affected by this disease. With respect to conditions with manifest edemas, occasionally the apparently paradoxical phenomenon can be observed that a lively diuresis sets in with partial or total disappearance of the edemas, if the retentions are temporarily increased by the sudden introduction of considerable amounts of water (Volhard's "Wasserstoss"). In an attempt to utilize this phenomenon and in the expectation that the antiretentional effects of the diet might manifest themselves if the retentions in Menière's disease are temporarily increased, the administration of quinine sulphate was chosen, Averbuck (5) having shown that it causes a significant liquid retention in the animal organism. Furthermore, the amount of the diuretically effective proteins administered in the diet was reduced below the level usually employed in antiretentional therapy in order to facilitate the development of such a temporary augmentation of the liquid retention. This was done in the expectation that, after the increased retention brought about by the administration of quinine sulphate and facilitated by the dietary measure of reduced administration of proteins developed, the still powerful antiretentional effects of a diet restricted in carbohydrates, fats and liquids would be sufficient to provide for the necessary diuresis.\* In fact, attacks of dizziness and headaches were observed on one of the first days of the therapy in all four cases, a manifestation of sudden increased liquid retention in the labyrinth and intracranially. A considerable polyuria was also reported by some of the patients, apparently a manifestation of elimination of retained liquids.

These occurrences, as well as the uniformly complete results obtained by a therapy designed as antiretentional, favor the assumption that Menière's disease, similar to the other pathological conditions of the group (epilepsy, etc.), develops on the basis of a disturbed water and mineral metabolism. In addition to this factor, however, it is necessary to postulate a local predisposing factor in the labyrinth, such as a local disturbance of the circulation therein. Attention should be called to the fact that it is necessary to postulate such a factor in certain cases of epilepsy, migraine, angina pectoris, etc., as well. Without this postulate the affection of only one ear could not be explained in Menière's disease.

If the view is accepted that Menière's disease develops on the basis of a disturbed water and mineral metabolism and a local unilateral circulatory disturbance in the ear, the following picture of the pathogenesis can be drawn. Under the influence of intrinsic factors, such as the endocrine system, gastric function, etc., or under the influence of extrinsic factors, such as the diet, atmospheric conditions, etc., liquid retention may develop. These retained liquids are

distributed over the entire organism, and the water content enclosed in both labyrinths also increases to a certain extent. If in addition to such an augmentation of the liquid content of the labyrinth as is due to the general retention, there is a further increase on one side due to a local predisposition (disturbed circulation), the endolabyrinthial pressure may increase to a level where the functions of the terminal parts of the nerve and sensory organ are affected, and dizziness develops. Furthermore, similar to the "mobilizational type" of attacks in epilepsy, migraine, angina pectoris, allergic diseases, gout, etc., it is also possible that in Menière's disease such local liquid retention may develop not when the retentions throughout the body are on the increase, but rather at precisely that time when the liquids accumulated in distant parts of the body become suddenly mobilized and start circulating. Part of these liquids would seem to pass through such parts of the body where there are no barriers, and they would thus seem to be eventually eliminated by the kidneys. In the labyrinth of the one ear, however, where, as postulated, a local circulatory disturbance exists, part of the liquid may be temporarily retained and lead to an attack. Both in this (mobilizational) type of attack as in that previously described which may be termed "retentional," the paroxysm would seem to come to an end when the locally retained liquids are released. These may then either be retained in other parts of the body where they manifest themselves in the form of other symptoms (headache, etc.), or be ultimately eliminated by the kidneys.

Since there are no available data as to the state of the general water and mineral metabolism in Menière's disease, it cannot yet be determined whether only the retentional or the mobilizational type or both may occur and, if the latter is the case, which type is the more frequent. From the fact observed by Dandy (6), however, that in only one of forty-two cases was there an intense desire to urinate during the attack, it seemingly follows that the mobilizational type is not the more frequent. Obviously the polyuria in this case might have been a result of the sudden mobilization of liquids.

On the basis of this concept of Menière's disease, the nausea and vomiting accompanying the dizzy attack may either be due to a so called reflex irritation, or to a simultaneous intracranial liquid accumulation. The frequency of complaints with reference to headaches independently of the dizzy spells in Menière's disease favor the latter assumption.

Menière's disease has been identified in the foregoing as belonging to that group of diseases which includes epilepsy, eclampsia of pregnancy, etc. However, in one respect it occupies a special position among these pathological conditions, i.e., while in epilepsy, migraine, angina pectoris, etc., there is usually a relapse within a few weeks after the antiretentional therapy is discontinued, in Menière's disease no relapse has been observed so far (longest observation over two years), although, as indicated, all antiretentional therapy was discontinued after approximately one month. This occurrence perhaps could be explained by assuming the existence of a vicious circle in the pathogenesis of Menière's disease, the development of which would be made possible by the presence of (1) a local lesion in the labyrinth and (2) a general disturbance of the water and mineral metabolism.

\*In other diseases of the group, the members of which have been previously enumerated and in which therapeutic results are to be had without such temporary augmentation of retentions, the antiretentional effects of larger amounts of proteins should be utilized.

The links of this vicious circle appear to be the following:

Local accumulation of liquids in the labyrinth due to generalized water and mineral retention and local circulatory disturbance—additional impairment of the local circulation due to posthydropic changes—further local liquid retention, etc. Through antiretentional therapy, as suggested, this vicious circle seems to be broken and the subsequent development of attacks thus prevented.

#### SUMMARY

A theory of the pathogenesis of Menière's disease and a therapy based on this concept is offered for further investigation and control. While the number of cases observed (four) is small, the complete disappearance of the attacks in all cases, with no relapses, is noteworthy. The significance of this observation is illustrated by the fact that, according to Dandy (6), "until the advent of sectioning of the auditory nerve there was no treatment, either curative or palliative, of Menière's disease that is worthy of mention."

#### CONCLUSIONS

1. Menière's disease seems to be caused by temporary local accumulation of liquids (in the labyrinth). Thus Menière's disease seems to belong in the group of diseases comprised by epilepsy, eclampsia of pregnancy, eclampsia of infancy, migraine, angina pectoris, bronchial asthma, allergic diseases, gout, etc.

2. Antiretentional therapy consisting of a diet and the administration of quinine sulphate, phenobarbital and extractum nucis vomicae was followed by cessation of the attacks in all (four) cases observed.

## ABSTRACTS

DR. K. UEBLEISEN.

*Dietetic Treatment of Chronic Gastritis. Therapie d. Gegenwart, June, 1934.*

The etiology of gastritis is manifold and the diagnosis of gastritis should be made only by careful exclusion of other pathology. He claims that irrespective of the amount of acids, or of increased motility, the important factor remains to put the glandular apparatus to rest. This is accomplished by repeated administration of weak teas, freshly prepared fruit juices, gruels, and the application of cataplasms upon the stomach. Hyper-acid cases clear up rapidly manifested by subsidence of hypersecretion, spasms and amelioration of pains. Salt free and lacto-vegetarian diet is very useful in these cases and sub and anacid varieties also respond favorably. In emaciated patients proper doses of insulin may help to restore the weakened function of the glandular apparatus. When dealing with true inflammatory gastritis of a more severe degree, rest in bed with an initial starvation is prescribed. In weak individuals hypodermoclysis with or without food is administered. Two or three days later the above prescribed diet is instituted gradually turning to light diets consisting of cakes and zwieback and compottes. Gastritis accompanied by abundant secretion of mucus responds favorably by a lavage before retiring. Later the partaking of alkaline waters is advisable. The diet continues to be scarce in sodium chloride and one may add purees, butter eggs, jellies, brains, sweet-breads, juices of vegetables, and salads. Milk is given only after the salt free diet has achieved its desired results. Then some salt may be given. Animal proteins are offered at first as fish. Naturally there are no condiments given. Such a salt free and non-irritating diet is followed by good results especially in achylic gastritis, where the tenacious gastrogenous diarrheas are often favorably influenced. To counteract such diarrheas, other procedures, the administration of calcium salts and jellies or a new apple diet should be

tried. The author gives one pound of grated apples five times a day, carefully eliminating the seeds and he claims results in two or three days. The effect is due supposedly to the tannic acid content.

CUTTING, REGINALD A., M.D., C.M., Ph.D.

*Absorption of Dextrose and Water by the Small Intestine and Colon. Arch. Surg., Vol. 29, No. 4, Oct., 1934, pp. 643-661.*

This article presents a review of the literature and a series of experiments as carried out in dogs on the absorption of dextrose and water from the small intestine and colon.

The opinion that dextrose is absorbed only slightly, if at all, by the colon does not seem to be supported by experimental evidence.

Hypertonic sugar solutions in the rectum cause water to be withdrawn from the intestine and this increase in bulk stimulates expulsive movement. It has been shown that actually less dextrose is absorbed from the lower part of the intestinal tract from a ten per cent dextrose or hypertonic solution than will be absorbed from an isotonic or five per cent dextrose solution. Hypertonic solutions interfere actively with the absorption of water as well.

Although the author feels that according to these experiments the lower portion of the intestinal tract under favorable conditions is capable of absorbing considerable quantities of dextrose and water and although proctoclysis can, therefore, be regarded as of definite clinical value, the amount of absorption of dextrose which occurs low in the intestinal tract is only a fraction of that which occurs in the jejunum. Rectal administration of dextrose is therefore only a relatively inefficient substitute for oral administration, and should be adopted only when for one reason or another oral administration is contraindicated.

N. W. Swinton, Boston.

## SECTION IV—Roentgenology

### Carcinoma of the Body of the Pancreas: A Clinico-Roentgenologic Diagnosis\*

By

MARTIN G. VORHAUS, M.D.  
NEW YORK CITY, NEW YORK

**T**HERE are many obscure clinical syndromes still awaiting recognition. Too many of these require post mortem study for their identification. However, not uncommonly, the clinician can arrive at an accurate concept of many of them by a close correlation of the clinical findings and the abnormalities revealed radiographically. This report is an illustration of the dove-tailing of such data.

Carcinoma of the pancreas is relatively uncommon. The incidence is given as 1.5% of all carcinomata (1). Its clinical recognition long has been delayed. Pathological studies show that the pancreas is the site of secondary invasion of carcinoma more frequently than it is the origin of a primary growth (2).

In the past few decades, many reports have appeared of the recognition of carcinoma of the head of the pancreas. This is the most likely location for a primary pancreatic carcinoma and occurs in 66-2/3% of all such pancreatic neoplasms found surgically (3). Autopsy statistics place its occurrence at the higher figure of 80% (4). It is not the greater frequency alone which has made carcinoma of the head of the pancreas a disease which is diagnosed often. The close relationship of the second portion of the duodenum and the common bile duct to the head has afforded tell-tale information.

It is accepted now that this disease should be suspected in a case of painless, deepening jaundice, usually in association with a small, firm liver and often, but not always, accompanied by an enlarged gall bladder. To these clinical facts is added the roentgen demonstration of an increased convexity of the second portion of the duodenum, to the right, producing a capital "C" configuration, and usually revealing a delay in the barium transit through this region. The dove-tailing of these clinical and roentgen findings have led many—and should lead more—to the early recognition of primary carcinoma of the head of the pancreas.

The pancreas apart from its head, is more rarely involved. Occasionally, the tail alone is the site of primary carcinoma: its recognition is extremely difficult. One observer (1, 5), reported only three such cases, seen in twenty-five years of search. Each of these gave the confusing roentgen findings of a large,

irregular, "infiltrating-like" lesion on the greater curvature of the stomach in the medio-gastric region, the shadow of which most closely resembled a gastric carcinoma. Operation and autopsy disclosed a primary carcinoma of the tail of the pancreas. The roentgen defect in the stomach was due to attachment or extension to this organ from the primary lesion.

The sole remaining site for carcinoma of the pancreas is its body, or mid-portion. A complete review of the literature reveals some reports (6, 7, 8, 9, 10, 11) upon the pathologic findings and suggestive clinical data. Several roentgen articles (12, 13, 14), in discussing the findings in carcinoma of the head of the pancreas and in pancreatic cyst, state that carcinoma of the body of the pancreas should show roentgen changes in the duodenum. However, this Author could not find a single report of the clinical and roentgen findings which would enable such diagnosis to be established. For that reason, this case is reported.

#### CASE REPORT

S. H., 59 year old male, admitted to the Medical Service on October 25, 1934, complaining of pain in the back, in the region of the lower thoracic vertebrae.

On August 11, 1934, he had been hospitalized in Brooklyn for the same complaint. He stated that he had had this pain for from four to five months. It was relieved by aspirin, associated disturbances were epigastric pain, constipation and a weight loss of twenty-five pounds during the preceding five months. The examination at the previous hospital (which included, in addition to the usual clinical and laboratory studies, roentgen films of the spine, the gastro-intestinal tract and the gall bladder), failed to reveal any positive anomalies; he was discharged on September 18, 1934, "with no positive findings and, in all probability was suffering with a myositis."

On admission here, the patient complained of a dull, nagging pain in the back, located in the region of the lower thoracic and upper lumbar vertebrae. The pain practically always was present; at times was severe, radiated up and down along the spine for short distances, but did not radiate anteriorly. Several months after the onset of the back pain, the patient stated that he experienced the same type of pain in the epigastrium and that this radiated straight through to the back pain; it was more severe when the back pain was increased. Both pains were greatly aggravated by walking but bore no relation to coughing, breathing, defecation or urination and little, if any, relation to food. Since discharge from the other hospital, he had lost more weight, the total loss being fifty

\*From the Medical Service of Dr. Albert A. Epstein, Hospital for Joint Diseases.  
Submitted February 9, 1935.

Fig. 1

pounds since the beginning of his illness. His weight, on admission, was 100½ pounds. Marked constipation was present. In addition, he complained of anorexia, increasing weakness and insomnia due to pain. There was nothing of significance in his past or in his family history. Syphilis was denied by name and signs.

The *physical examination* revealed a markedly emaciated, elderly, white male who, although weak, was oriented and cooperative. The head and neck revealed no significant findings except for a thickly coated tongue and dry lips. The fundi showed moderate arterio-sclerotic changes. The cardiovascular system showed moderate arteriosclerotic changes although the heart was enlarged only slightly, and the blood pressure was 126/90. The lungs were negative except for some dullness at the left apex and some harsh breathing at this point.

The *abdomen* was scaphoid and tense. There was some tenderness, on deep palpation in the epigastrium but no mass was palpable. The liver was enlarged from one to two fingers' breadth below the costal margin and the edge was smooth and firm. No other abnormalities were present in the abdomen. There was slight tenderness, posteriorly, over the eighth, ninth and tenth dorsal vertebrae and at the costo-vertebral angles. The remainder of the examination revealed nothing of significance.

The *clinical impression* was that of unidentified malignancy and a diagnostic survey was instituted. The neurologist (Dr. Rosenheck), expressed the opinion that there was no primary neurological condition to account for the pain. The urine revealed nothing of significance. Fractional gastric analysis gave figures within normal limits.

Fig. 1. Immediate Film.

The blood counts ranged from 75 to 90% hemoglobin, 4.6 to 5.3 million r. b. c., 10 to 16 thousand w. b. c., with a relatively normal differential count. Serological tests were negative, as was the blood chemistry.

*X-ray of the chest* showed only a thickened pleura at the left apex and some increased sclerosis of the aortic arch. X-ray of the lumbosacral spine and pelvis disclosed no definite evidence of a metastatic neoplastic process. There was a sacralization of the fifth lumbar vertebrae on the left side with moderate arthritic changes in the vertebral segments. (Dr. Pomeranz).

*X-ray of the gastro-intestinal tract* gave the first real clue to the diagnosis. There was no apparent intrinsic disease of the stomach (Fig. 1). There was increased peristalsis with a tendency towards segmentation. A dotted line has been drawn on the film to show the probable outline of the greater curvature of the antrum. The duodenal cap is moderately dilated and shows no defects. The descending portion and the beginning of the transverse portion of the duodenum are markedly dilated. To the left of the third lumbar vertebrae can be seen a well filled duodenal-jejunal junction which appears normal. Figure 2 is a three hour observation and shows that the stomach is almost completely empty. There is a mass of barium located at the level of the third and fourth lumbar vertebrae, slightly to the right of the mid-line, which seems to be in the duodenum. This is more apparent in the six hour film (Fig. 3), at which time the descending portion and beginning of the transverse portion of the duodenum are seen clearly, filled with barium and slightly dilated. The descending portion of the duodenum shows no loss of its normal markings, and its configuration and position are

Fig. 2

Fig. 2. Three Hour Film.

Fig. 3

relatively within normal limits. The remainder of the gastro-intestinal series revealed no abnormalities and a detailed description of the other films is unnecessary.

#### DISCUSSION

The roentgenologic signs indicated a partially obstructing lesion at the beginning of the transverse portion of the duodenum. The dilatation of the second portion of the duodenum and the partial dilatation of the cap, and the vigorous gastric peristalsis, all indicated a slowly developing obstruction. This suggested a slowly developing tumor and since the only organ of importance at that exact site is the pancreas, suspicion was directed to a neoplasm in this organ. The next question was the exact location of the tumor. The site of the obstruction indicated very clearly that it was in the mid-portion. The films, as indicated in the figures above, all showed a normal configuration of the descending or second portion of the duodenum, that is, there was not an increased convexity of the second portion producing the capital "C" configuration which is typical of carcinoma of the head.

The next step was the correlation of the clinical data. The absence of jaundice and of a palpable gall bladder militated against the diagnosis of involvement of the head of the pancreas. For these reasons, it was held justifiable to postulate a primary carcinoma, starting in the body of the pancreas and not involving the head.

Fig. 3. Six Hour Film.

The clinical course was rapidly downhill with increasing loss of weight, weakness, inability to eat and diarrhea. There was a temporary improvement following the administration of intravenous glucose solutions but, within a few days thereafter, the patient became moribund and *exitus* occurred without elevation of temperature or pulse rate. Death occurred on December 5, 1934, six weeks after admission.

An autopsy was performed four hours after death (Dr. S. A. Jacobson). Excerpts from the protocol which are pertinent only are given.

**Heart.** The epicardium is everywhere smooth and glistening. A large area over the right ventricle is white and thickened. The small quantity of pericardial fat which is present has been converted into an edematous mass (serous degeneration). Coronary vessels are tortuous and very thick and sclerotic to palpation. On section, myocardium is dark brown and firm. Walls are of normal thickness, but all cavities are diminished in size. The mural endocardium is everywhere transparent. All valves are thin and delicate with the exception of the aortic. One of the commissures of this valve shows a moderate degree of fusion with thickening and hardening of adjacent portions of the cusps. Otherwise, there is no thickening or calcification, even in the mitral ring. All branches of both coronaries show very marked thickening and hardening of their walls, although complete occlusion of the lumen is nowhere demonstrable.

**Lungs.** Both are rather large; except for some consolidated areas in the right, they are crepitant, albeit slightly edematous, to palpation. Apices shows some thickening of the pleura. Firm pleural nodules can be felt in the upper portions of the organs, and, in diminishing numbers for a considerable distance downward. On section, the parenchyma is for the most part bright pink and wet. The parenchyma of the apices, however, is dark gray and more or less solid in appearance. Irregular areas of the middle and lower lobes of the right lung reveal upon close inspection areas which are firmer and slightly raised and granular. Bronchial mucosae are smooth; in the lumina is found some thin whitish matter. Pulmonary vessels show nothing noteworthy.

**Liver.** The organ is decidedly reduced in size. On the surface and in the interior are numerous large, sharply demarcated, white tumor nodules which stand out from the cut surface. The parenchyma is dark reddish brown; lobules are clearly demarcated. The gall bladder is considerably distended, as also is the common bile duct. Their walls show no abnormality; they contain thin green bile.

Fig. 4. Photomicrograph of the Primary Carcinoma in the body of the Pancreas removed at autopsy.

Fig. 4

**Suprenals.** That on the right is normal in size and shape. The cortex is rich in brown matter. That on the left is infiltrated by direct extension with the tumor mass of the adjacent pancreas.

**G. I. Tract.** The esophagus shows nothing noteworthy; stomach contains some greenish fluid; its mucosa is slightly congested; duodenum shows nothing unusual, its mucosa is pale and smooth. The jejunum and ileum are similarly negative, except for the presence of a diverticulum measuring approximately 4 cm. in length, situated approximately 1 meter cephalad of the ileocecal valve. The colon shows nothing noteworthy.

**Pancreas.** The head of the organ is soft, lobules pulling apart readily. The body and tail, however, have been destroyed and replaced by an irregular mass of very hard, white tissue in which yellow areas are visible. This mass does not extend into adjacent structures, with the exception (left suprarenal) noted above.

**Blood Vessels.** The aorta, throughout its length (with the exception of the ascending portion) bears numerous, yellowish and, particularly about the mouths of the intercostal arteries, whitish plaques. A few of these in the lowermost portion are ulcerated. Hardly any of them are brittle. Vena cava and portal vein are smooth; the latter is slightly distended.

**Lymph Nodes.** Those of the hilum of the lungs are large, gray and firm. Those in the vicinity of the pancreas, particularly about (and pressing on) the bile ducts, are infiltrated with white tumor tissue, as are some of the more distant mesenteric nodes.

#### ANATOMICAL DIAGNOSIS

1. Carcinoma of the body and tail of pancreas, with direct extension into left suprarenal gland and metastases to liver and regional lymph nodes.
2. Coronary arteriosclerosis.
3. Brown degeneration of heart and liver.
4. Chronic passive congestion of viscera.
5. Chronic (inactive) pulmonary tuberculosis of both apices.

**Microscopical.** Section of the pancreas (Fig. 4), shows part of it to be in a good state of preservation, except for

a slight degree of fibrosis. There is, however, a large amount of tumor tissue, as indicated in the gross study. This is in part divided from the surviving pancreatic tissue by a thick fibrous septum; in part, however, it has crossed this boundary and infiltrates the parenchyma freely. The tumor consists of glandular elements made up of moderate-sized, somewhat hyperchromatic and pleomorphic, polyhedral cells. Giant cells are very numerous. The architecture is extremely irregular. The amount of fibrous tissue is very variable. Large areas of tumor are completely necrotic.

#### SUMMARY

The outstanding clinical facts were a marked loss of weight, appetite and strength, increasing cachexia and the development of an unexplained persistent and increasing pain located at the level of the lower dorsal vertebrae and radiating up and down the spine for short distances. Later, an identical type of pain, located in the epigastrium, developed which radiated through to the region of the back pain. Both of these pains were aggravated by walking. The roentgen findings demonstrated no osseous change in the dorso-lumbar spine. The gastro-intestinal roentgen examination revealed a partial obstruction at the beginning of the transverse (third) portion of the duodenum with dilatation of the descending portion of the duodenum and of the cap, and increased gastric peristalsis, indicating gradually developing obstruction. Based upon these clinical and roentgen findings, a diagnosis of carcinoma of the body of the pancreas was made. This diagnosis subsequently was verified at autopsy.

#### CONCLUSIONS

1. A case of carcinoma of the body of the pancreas is reported.
2. The diagnosis was made on the basis of the clinical and roentgen findings, and verified at autopsy.
3. It is believed that this is the first case of its kind to be reported.

## ABSTRACTS

SAPOZNIK, H. J.; ARENS, R. A.; MEYER, JACOB, AND NECHLES, HEINRICH

*The Effect of Oil of Peppermint on the Emptying Time of the Stomach. J. A. M. A., 104:1792, May 18, 1935.*

The authors have previously reported that oil of peppermint diminished gastric acidity. In this study they report the effect of oil of peppermint on the emptying time of the stomach. In the empty stomach small doses of oil of peppermint had no effect on the hunger contractions of dog or man. Large quantities of oil of peppermint decreased the motility in six tests and produced no change in two.

In experiments with a meat meal and oil of peppermint, shortening of the emptying time was observed.

In six normal young females the addition of two cc. of oil of peppermint to a barium-milk shortened the emptying time of the stomach as observed fluoroscopically.

These studies seem to explain the popular use of oil of peppermint in many stomach remedies. The use of peppermint candy and peppermint alcohol after a heavy meal appears useful because by increasing motility distension and fullness are relieved more promptly.

# Diverticulum of the Stomach\*

By

ELLIS B. FREILICH, M.D.

GERHARD DANIELIUS, M.D.

GEORGE C. COE, M.D.

CHICAGO, ILLINOIS

**D**IVERTICULA of the stomach relatively are uncommon. They occur in the stomach less frequently than in any other part of the gastro-intestinal tract, with the exception of the jejuno-ileal region.

The first case, pathologically, was reported by Helmont in 1804, Akerlund reported the first case, roentgenologically, in 1923. Since that time, 108 cases have been recorded. In a recent article by Drs. River, Stevens and Kirklin, the subject is statistically reviewed. To the already existing literature they add a series of 33 cases from the Mayo Clinic, of which only 19 were proven as true diverticula.

It is our purpose to report another case accompanied by complete X-ray studies. The diagnosis here was made without surgical aid. We were able, therefore, to go back and re-question the patient in an effort to determine whether or not a typical or a suggestive clinical symptomatology exists to help in future diagnoses. With this in mind, we have also carefully reviewed all the literature with particular study of the case reports. We are mainly concerned with this question for future assistance clinically.

## CASE REPORT

The patient Mrs. M.T., age 29 was first seen by Dr. E. B. Freilich. She complained of cramp-like pains localized to the middle of the abdomen. These pains had recurred at irregular intervals over a period of ten years but always during the fall season. Under codein medication the pains subsided.

On December 15, 1934, the patient was again seen because of severe, excruciating pain in the epigastric region. As much as a half grain of morphine hypodermically was required to control the pain. On the following day the patient was admitted to the medical service of Dr. Freilich at the Mt. Sinai Hospital.

At this time she volunteered the information that she had experienced a similar attack about ten years previously. Since that time, she has had the recurrent attacks of abdominal cramps. The pains were not influenced in any way by food or fluids of any kind, and they were in no way related to the gastric cycle.

Her appetite was excellent and there was no loss in weight. No history of nausea, emesis, hematemesis, jaundice or melena was elicited. The bowel function was fair with a slight tendency toward constipation.

Systemic enquiry was essentially negative. In 1919 she had a tonsilectomy and a submucous resection. As a child she had pleurisy with an endocarditis, but no residual effects were determined.

*Physical examination* revealed a white female, not acutely ill, but markedly nervous and apprehensive. Head, eyes, ears, nose and throat essentially were negative. The heart and lungs were normal in function and action. The abdomen was soft and relaxed with no pain, tenderness or rigidities.

*Laboratory studies* all were negative. Blood pressure was 106/64. Blood chemistry showed 82 mg. sugar and 9

mg. urea nitrogen per 100 cc. blood. Gastric aspiration, after an Ewald test meal, revealed no free hydrochloric acid and but 14 cc. total acidity. Basal metabolic studies were normal with rates of  $+2$  and  $-3$ ; E. K. G. was normal. The blood count showed 100% hemoglobin, 4,120,000 red cells (I.I.I.), 8,100 white cells with 63% polymorphs, 31% small lymphocytes and 3% eosinophiles. Wasserman and Kahn tests were negative; urine examinations were repeatedly normal.

*Gastro-intestinal X-ray studies* were made and since the diagnosis was roentgenographic rather than clinical, we are quoting Dr. Danielius' report:

"The barium meal passes normally through the esophagus and the cardia. With the very first swallow an unusual globular shadow is visible closely below the entrance of the esophagus into the stomach. It is a perfectly round pocket the size of a hazelnut situated on the lesser curvature, close to the posterior wall of the stomach and is well visualized in all the different positions and directions.

The mucosal pattern of the stomach appears to be completely normal; the rugae soft and sharply limited. Upon complete filling the stomach is seen to be of the fishhook type, the lowermost point being about  $1\frac{1}{2}$  inches below the iliac crest. The outlines are sharp in all respects, and the tonus is good. The peristaltic waves run normally along both curvatures as far as the pylorus. The expulsion begins normally. The pylorus, the duodenal cap and the other parts of the duodenum appear completely normal. All parts are freely movable and no pain is elicited upon pressure.

The films very clearly substantiate the fluoroscopic findings. On the film, taken in the recumbent position, small, soft and well defined rugae are visible leading into the diverticulum ("schleimhautschicne"). Furthermore the whole mucosal pattern of the stomach is soft, well defined and shows no evidence of irritation.

*On the three hour study* there was an isolated filling of the above described round shadow pocket. Otherwise the stomach had emptied itself completely and the cecum was beginning to fill out.

*On the 24 hour study* the colon was filled from the cecum as far as the descending colon; all parts showed a normal position width, haustrations and sharp outlines.

*The X-ray findings indicate a diverticulum of the stomach* about the size of a hazelnut near the cardia on the lesser curvature close to the posterior wall. No pathologic findings or other diverticula are present elsewhere in the gastro-intestinal tract."

## ROENTGENOGRAPHIC DISCUSSION

In this case we had to decide whether the X-ray findings indicated a penetrating ulcer or a diverticulum. Our reasons for the latter diagnosis follow:

1. The localization closely below the cardia on the lesser curvature more posteriorly is typical for diverticulum. Such anomaly rarely is encountered elsewhere in the stomach. Though an ulcer niche occasionally

\*From the Medical and Roentgenological Services, Mount Sinai Hospital. Submitted March 3, 1935.

Fig. 1

may be found in this locality, its occurrence is extremely uncommon.

2. The so called "*schleimhautschiene*" (mucosal tract) in the neck of the diverticulum is typical for all diverticula of the gastro-intestinal tract, and corresponds anatomically with a normal, non-involved mucosa. This is not the finding in a penetrating ulcer, where as a rule, the mucosa is destroyed or infiltrated.

3. The regular, perfectly round shape of the shadow suggests a diverticulum, but does not absolutely rule out an ulcer.

4. The complete lack of a gastritis ("*begleitgastritis*") aids in the diagnosis. An ulcer niche of the type of this shadow probably would be combined with findings of a gastritis.

#### CLINICAL DISCUSSION

Diverticula of the stomach may be of congenital (true) or acquired (false) type. The true diverticulum involves all the layers of the stomach and implies intact muscular and mucosal layers. In the acquired type one coat is absent.

Various hypotheses are offered, but the consensus of opinion favors the congenital formation of true diverticula.

The average *age group* in the series studied at the Mayo Clinic was about 42 (25-59) years. Our patient was 29. Diverticula occur with equal frequency in both sexes. The *anatomic location* is typically in the cardia just below the esophageal junction on the lesser

curvature near the posterior wall.

Fig. 1. Upper part of the stomach in the upright position. Filling with a small amount of barium. On the lesser curvature near the cardia (on the fluoroscopic view close to the posterior wall) the perfectly round regular pocket is visible, superimposed by a small air-bubble. Mucosal pattern soft, regular and sharply limited.

curvature near the posterior wall.

Carefully reviewing the literature of case reports, we find that there are no typical symptoms clinically pointing towards the underlying pathologic anatomy in the stomach, but there are certain suggestive clues. The patients' complaints cover long periods of time. There are intervals of long duration in which the patients are absolutely symptom free. When the symptoms arise, they come suddenly and equally abruptly disappear. There seems to be a certain periodicity of attacks. The symptoms as a rule are vague (a sense of epigastric discomfort, substernal fullness and stinging, cramp-like distress) and are in no way related to the kind or character of food eaten.

In analysing this question, we find several reasons for the lack of a typical symptomatology.

1. Only in the last few years has it been possible to make the diagnosis of a diverticulum of the stomach without the aid of surgery. In the past most of these were discovered at autopsy, but with the advent of the X-ray, diverticula can be "picked up" early. The number of physicians having had the opportunity to re-question the patient in the light of X-ray diagnosis is still rather small.

2. The types of diverticulum, anatomically, have not yet been subdivided. The symptoms or lack of symptoms will depend upon the width and the length of the neck of the sac, any associated pathology, etc.

Fig. 2

Fig. 2. Stomach in the recumbent position. The shadow-pocket now crescent-shaped but again perfectly regular. The "*Schleimhautschiene*" (mucosal tract) on the neck of the diverticulum well visualized. The mucosal pattern of the whole stomach soft, regular and presenting no signs of irritation.

A diverticulum having a large neck and no associated irritation of the mucosa, which fills and empties easily, obviously will give rise to few or no symptoms. A diverticulum with a narrow neck, with or without any signs of irritation, may give rise to symptoms. The latter also may be true if there is swelling of the mucosa in the neck delaying or retarding the emptying of the cavity.

3. A true diverticulitis, or even an ulcer in the diverticulum, will give rise to symptoms. Roentgenographically this would be difficult to differentiate from a true ulcer-niche.

## CONCLUSIONS

We are reporting another case of diverticulum of the stomach. The diagnosis here was not made clinically and up to the present time, pre-operatively or ante-mortem can only be made roentgenographically. We feel that by means of the X-ray the diagnosis can be made sufficiently early to give the clinician an opportunity of carefully studying these cases in the hope of building up a symptomatology which will be suggestive, if not diagnostic, of this condition. The matter of differential diagnosis between a diverticulum and an ulcer is important inasmuch as surgical indications are dependent upon the type of pathology present.

# ABSTRACTS

DR. F. GALLART MONES.

*Gall-Bladder Response to Different Stimuli as Detected by Cholecystography, Gaceta Medica Espanola, March, 1935, Vol. IX, No. 6.*

The author concludes after several tests with fats, peptone, plain water, glucose, barium sulphate, dilute hydrochloric acid, hypophysis and adrenalin, that the gall-bladder empties more readily and more quickly with fats than with anything else. He admits that the shadow of the gall bladder becomes smaller after the administration of Magnesium sulphate, through a duodenal tube, but the decrease in size is much more pronounced after fats. Although he believes that patients with gall-bladder disease are benefited by gall-bladder drainage (Meltzer-Lyon), he is of the opinion that the emptying of the gall-bladder alone does not produce this benefit, but that some other factor, perhaps the action of the  $MgSO_4$  on the liver cells, plays an important role.

Juan Rodriguez, Fort Wayne.

RUTLEDGE, C. P.

*"The Diagnosis of Diverticulitis and Diverticulosis of the Colon, with Special Reference to the Roentgen Study of These Conditions." South. Med. Journ., 28:303-309, April, 1935.*

Diverticulosis is defined as the presence of one or more diverticula without symptoms or the presence of inflammatory reaction referable to the diverticula. The presence of diverticula with accompanying symptoms or inflammatory reaction constitutes diverticulitis. The incidence of diverticula has been found to be about one case in every

eighty routine gastro-intestinal examinations. The most frequent location in the colon is in the rectosigmoid region but any portion, even the appendix, may be the site of involvement.

Most cases occur in patients past 40, and usually in men who are overweight and victims of chronic constipation. Diverticulosis generally produces no symptoms. Diverticulitis is evidenced by abdominal discomfort or pain usually about or below the umbilicus particularly to the left and bearing no relation to the intake of food. Constipation is the rule. Bladder irritability frequently accompanies tenderness in the lower abdomen. Muscle rigidity varies. There is often a low grade fever and moderate leucocytosis. Hemorrhage is rare and should suggest the possibility of malignancy. The symptoms may become aggravated or subside.

In the X-ray examination the combined use of the meal and enema give the most information. The enema alone is used in subsiding acute cases or those showing partial obstruction. It is well to remember that there may be several days delay in the filling of the diverticula in rare cases. Areas of spasticity of the colon with numerous serrations (saw tooth deformity) may be the earliest signs of the development of diverticula. In the differential diagnosis the following conditions are discussed—carcinoma of sigmoid, left sided appendicitis, cholecystitis, sigmoiditis, actinomycosis, syphilis, and hyperplastic tuberculosis. A well selected list of references is given.

J. Duffy Hancock, Louisville.

## SECTION V—*Therapeutics*

### Treatment of Hemorrhage Caused by Peptic Ulcer

By

G. A. HENDON, M.D.  
LOUISVILLE, KENTUCKY

NOTHING is more alarming than a copious hemorrhage from an unseen source. No other catastrophe creates such a deep sense of futility in the mind of the physician who is responsible for the patient's welfare.

In hemorrhage from gastric and duodenal ulcers the source of the bleeding in both is invisible and uncertain. Blood simply cascades from the mouth or from the bowel or both simultaneously. The patient becomes cold and blanched and swoons into unconsciousness. The pupils dilate and the respiration becomes slow and shallow and the victim presents almost a perfect picture of dissolution. Blood from the stomach is colored a deep dark red which distinguishes it from that which comes from the lungs. It is often mixed with particles of undigested food. It is a never-ceasing source of wonder that one can lose such apparently large quantities of blood and survive the ordeal. The burden of discretion rests very heavily upon the physician in the case at this particular point and the choice of a proper and safe procedure in the circumstances creates a serious quandary for the medical attendant. The patient presents a very dismal prospect for surgery on account of the acute anaemia and its concomitant infirmities. On the other hand, it seems like unpardonable timidity merely to stand by and watch a patient bleed to death without exerting an effort toward his relief. The medical measures that we have available are so meager that they do not inspire either hope on the part of the patient or confidence on that of the physician.

We have become convinced that there is an efficient solution of the problem furnished by venoclysis when it is used sincerely and appropriately. Complete rest for the stomach is, thereby, secured and the organ contracts into a hard mass which plugs the vessels and controls the bleeding, if allowed to remain in force as much as ten days. All evidences of gastric disease disappear if the ulcer is not malignant. In support of this statement I beg to submit the following twelve cases of hemorrhage which have occurred as the leading symptoms in my series of forty-six cases of gastric and duodenal ulcer treated by venoclysis.

*Case I.* was a physician, age 53, of the stout and robust type. Had had his gall bladder removed and a gastroenterostomy to control hemorrhage three years previously by another surgeon. In the interval he had suffered consider-

able digestive trouble. Was restricted to a diet. Suddenly on Oct. 26, 1932, he collapsed from the effects of a copious hemorrhage. He lost consciousness, became pale and apparently lifeless. His body surface was cold and clammy. He vomited blood and passed large quantities per rectum. His pulse was soft and feeble and he had sighing respiration and gasped for breath. The question of moving him to a hospital was seriously debated on account of the apparent hopelessness of his condition. He was removed however and on his arrival there his blood count showed the red under two million and the hemoglobin 60%. He was immediately started on venoclysis, 10% Glucose in Ringer's Solution and 10 cc. of 10% calcium gluconate was added to each 800 cc. of the Solution.

A diagnosis of marginal ulcer had already been established by X-ray examination. In January, 1934, he had a slight hemorrhage from the bowel. With that exception he has been perfectly well to date, has been symptom-free and weighs 175 pounds: a gain of 45 pounds since his illness and is actively engaged in the practice of medicine.

*Case II.* H. G. E., age 52. After an indefinite period of gastric symptoms he suddenly became dizzy and nauseated and vomited blood copiously, also passed large quantities from the bowel. This began on Feb. 15, and continued through February 16 to extreme weakness and unconsciousness. On February 17, he was removed to the Deaconess Hospital and treated by Dr. R. L. McCormack who exhibited venoclysis. Continued it ten days. Hemorrhage was immediately controlled. All symptoms finally subsided and March 17 he was up and around and on April 15 he weighed 165 pounds. He since resumed his work, has been entirely free from gastric symptoms. It is now three years since his illness.

*Case III.* W. H. W., age 31. Admitted to St. Anthony's Hospital December 18, 1932. Symptoms began four years previously and continued with more or less severity. Two and one-half years ago patient suffered a rather severe hemorrhage followed in a few days by a second. He was temporarily relieved by a Sippy diet treatment. Venoclysis was begun on December 18, 1932, following his third and last hemorrhage. It was continued ten days. He left the Hospital January 14, 1933. He has regained his normal weight and resumed his occupation. Has remained symptom free up to now.

*Case IV.* W. E., age 59. Admitted November 17, 1931. Had peptic ulcer and hemorrhage ten years ago. Has had stomach trouble in varying degrees of severity since then. Present attack began on November 17, 1931. Was brought to hospital in collapse and unconscious. Pulse could hardly be felt at the wrist. Patient was cold and very pale. Venoclysis was immediately begun. There was a prompt reaction on the part of the patient. His progress toward recovery was unbroken. He left the hospital in two weeks.

Venoclysis continued five days. He has gained forty pounds and has remained well up to this time.

*Case V.* A. Z., age 41. Admitted March 29, 1931. Patient has been complaining of "stomach trouble" the past ten years. Has had copious hemorrhages at irregular intervals during the past four years. More frequent and copious during the past year. When admitted to the hospital his R.B.C. was 900,000. Hemoglobin 18%. Venoclysis was begun immediately after his admission. On April 2, a blood transfusion with citrated blood was given through the venoclysis attachment. 500 cc. taking about four hours to give it. He immediately became very restless and became delirious and died on April 4. He had been quiet and composed until the blood transfusion was administered. No post mortem was obtained.

*Case VI.* H. H. A., age 59. Admitted February 22, 1930. Died two hours after admission. Gastric hemorrhage. Diagnosis Peptic ulcer. This patient had a perforation of his ulcer three weeks previous. Was treated by venoclysis and apparently recovered. At that time he had considerable peritonitis was very low in vitality and a surgical operation did not seem advisable. He apparently recovered and was home about one week when he was suddenly seized in the night with abdominal pain and passed large quantities of blood from the bowels. He was taken to the hospital immediately but his condition was so grave on arrival that active measures did not seem justified. Venoclysis therefore was not begun. This case is included because three weeks previous venoclysis had been employed. No post mortem was obtained.

*Case VII.* Jesse B., age 25. Admitted June 11, 1929. Sent to hospital on account of gastric hemorrhage. Seven hours after admission he had a copious hemorrhage from the bowels and for a time pulse could not be felt at the wrist. Venoclysis was started immediately and continued until June 19. Had return of epigastric pain June 20 and 21. Venoclysis again exhibited and continued until June 25. Patient left the hospital June 27 and has remained well and symptom free to this date.

*Case VIII.* Geo. S., age 27. Admitted September 21, 1931. Severe gastric hemorrhage. Diagnosis peptic ulcer. Since May, 1931, patient has had numerous hemorrhages accompanied by much nausea and vomiting. Has had retinal hemorrhage in both eyes. Venoclysis used seven days. November 17, 1931, patient was dismissed from the hospital. Patient has remained well since that time and now seems normal in every way.

*Case IX.* Leo M., age 30. Admitted June 2, 1934. Very severe gastric hemorrhage two days before admission. Diagnosis: Peptic ulcer. Pain in epigastrium for the past year. Pain and nausea appear soon after he takes food although appetite has been good. Highly seasoned food causes the most pain. Has noticed tarry stools on numerous occasions during the past three months. Symptoms have increased recently both in frequency and severity. He was discharged from the U. S. Navy on account of T. B. pleuresy. He uses alcoholic drinks to excess. This is the only case in this series in which the X-ray failed to show evidence of lesion. The clinical symptoms were so positive that I can not escape the conclusion that he had an ulcer. Venoclysis was begun June 3, 1934, and discontinued June 11, 1934. He left the hospital June 16, 1934. Although he has resumed his drinking habits, he remains free of symptoms and has gained thirty pounds. I predict from him an early relapse of symptoms.

*Case X.* P. K., age 48. Admitted February 28, 1929. Diagnosis: Peptic ulcer. Has had gastric symptoms seven years. Has epigastric pain which occurs one to one and one-half hours after meals. Ingestion of food or soda gives relief temporarily. Pain occurs frequently at night about an hour after going to bed. Has had five copious hemorrhages from the bowels in the past four years. The last one occurred one year ago and was the most severe of all. Drinks alcoholics to excess. Gets on protracted sprees, when he can obtain the money. He had venoclysis from

March 1, 1929, to March 7, inclusive. He left the hospital March 15. His symptoms were relieved. However, he resumed his drinking habits and died two years later of delirium tremens and pneumonia combined, having had several intestinal hemorrhages in the meantime.

*Case XI.* F. S., Louellen, Ky., age 43. Mine Supt. Treated at Harlan Hospital July, 1934. Referred by Dr. W. M. Martin. Without warning this patient was taken suddenly ill with violent hematemesis. I saw him about twelve hours later, he was then unconscious, very pale and pulse could scarcely be distinguished at the wrist. Venoclysis was immediately begun and I returned to Louisville after giving explicit instructions in regard to the management of the case and the conduct of venoclysis. The patient made steady progress toward recovery and later regained his weight and resumed his occupation and has remained well since then.

*Case XII.* Mrs. M. L., age 66. Admitted January 4, 1930. Nurse by profession. Severe hematemesis. Peptic ulcer diagnosed. Vomited a large quantity of blood, some of it clotted. Venoclysis immediately exhibited and continued five days. Hemorrhage promptly controlled and general improvement was established and she left the hospital January 20. Resumed her occupation as professional nurse. She appeared to have made a complete recovery. February 17, 1935, five years after her treatment, she called me to her, where I found her prostrated from a severe gastric hemorrhage. She was immediately removed to the hospital and venoclysis begun. She had some bleeding the first day. Then all bleeding stopped. Her temperature assumed high peaks, 104-105-106; venoclysis was discontinued on the third day. The patient died five days after admission. Post mortem disclosed an ulcerating cancer and her intestinal tract filled with clotted blood.

#### COMMENT

In all cases 10% Glucose in Ringer's Solution or normal Salina was the solution employed. Dilaudid in small doses was used as needed for its quieting effect.

The four deaths occurring in this series might be analyzed as follows: Case XII, was 66 at the time of the first treatment, was free from symptoms five years and died at 71, from cancer of the pylorus and hemorrhage.

Case X, lived three years and died of alcoholic excess and pneumonia.

Case V, was bled down to 18% hemoglobin and less than a million red cells when admitted.

Case VI, was beyond human aid when seen and did not have venoclysis.

The other eight cases so far as I can determine are restored to their normal state of existence.

Although I have done so previously, it might be appropriate at this junction to offer an explanation in regard to venoclysis. I quote the following from my paper read at the annual session of The American Medical Association, June 25, 1930:

"Venoclysis is a term which I have employed to designate for the biologic and continuous administration of physiologic and therapeutic solutions directly into the blood stream." My experience with this "means of grace" covers almost the entire range of surgery. We have been able to support life and maintain a fair degree of physical prosperity for as much as three weeks at a time, to the exclusion of all other sources of nutrition. We have used it for the treatment of forty-six cases of gastric and duodenal ulcer which includes the twelve cases herein reported. In this series we had only one death besides those reported in this paper and that particular patient proved to be a cancer instead of an ulcer.

In all my cases X-ray studies have been made to verify the diagnoses.

I am convinced that venoclysis as a routine treatment for bleeding gastric and peptic ulcer is preferable to any yet presented. The risk is less, the time is shorter and the cures forty-one out of forty-six treated is better than any other statistics yet reported. I am greatly strengthened in my belief when I consider that my histories extend back six years.

The subsequent treatment after venoclysis has been discontinued, consists in certain gradations of restricted diet, beginning with liquid the first day then soft diet, light and given at regular intervals. The patient is instructed after returning home to avoid coarse articles of food or substances that may traumatize the mucous membranes. Perhaps celery might be classed as an example of what I mean. All fibrous or harsh substances are prohibited. We find the patients

are very happy if allowed such things as rice, mashed potatoes, toasted bread, puddings, eggs, chopped meat, fish or chicken, etc. I had one patient who gained a pound a day after returning home on squirrels and mashed potatoes and he shot the squirrels himself.

My experience in checking the chemical reaction of the gastric secretions leads me to the conclusion that the administrations of alkalies to secure and maintain alkalinity is not justified by the evidence. The clinical progress of my patients has not been influenced either way by their gastric juice reactions. Some of my cases have become alkaline in their gastric chemistry and remain so throughout, some have retained their acidity, some have changed from alkali to acid and no difference could be observed in the progress toward recovery. All our cases of marginal ulcer were alkaline in the beginning and later became acid but had relief of symptoms.

6. Elston L. Belknap, M.D.—Control of Lead Poisoning in the Worker. *J. A. M. A.*, Vol. 104, No. 3, p. 205.

The newer knowledge in this field relates to the metabolism of lead especially in regard to its deposition in bone and its excretion in feces and urine, the methods of artificial deleading and the modern prophylaxis in industry by periodic examinations of blood and urine. The essential points may be summarized as follows: 1. Lead is ingested in food in a daily amount of .176 mg. to .25 mg. About the same amount is excreted daily in the feces and a daily amount of .05 mg. to .1 mg. (observations on medical students) is excreted daily in the urine. Hence normally a leadequilibrium is established. 2. With excessive lead intake there is retention, e.g., 473 mg. ingested gave an excretion of 69 mg. in 46 days. 3. Lead is found as a soluble diphosphate in the blood and like calcium is deposited within a few days in the bones as an insoluble tertiary phosphate. 4. Mercury and radium like lead and calcium are absorbed by and deposited in bone. The metallic salts are deposited in the trabeculae in narrow especially of the epiphyses. 5. Lead and calcium are stored or withdrawn from the bone simultaneously and under similar conditions. 6. Lead stored in bone is not toxic except possibly as a cause of dental caries. 7. Excretion is mainly through the feces, less in the urine. The quantitative estimation of lead however is more practical in the urine. 8. Lead excretion may be hastened by acid producing agents especially ammonium chloride and phosphoric acid. High calcium intake in diet or by intravenous injection reduces lead excretion and controls toxic episodes. 9. Calcium gluconate, intravenously 210 cc. of 10% may give a very dramatic relief in acute lead colic

or other symptoms. Fifty cubic centimeters of 5% calcium gluconate intravenously every four hours for two days have been used, then less frequently and finally by mouth. 10. Parathyroid extract and viosterol increase the excretion of lead, mercury and radium. 11. Metabolic crises and acute infections release lead from bone trabeculae. 12. Lead can be "pulled" from bone two years after known exposure has been stopped. 13. Artificial de-leading should be done one to four weeks after the subsidence of acute symptoms by low calcium diet and by the administration of ammonium chloride or phosphoric acid, aided if necessary, by parathyroid and viosterol. Ten cubic centimeters of ten percent phosphoric acid may be given in diluted form every hour for ten doses and magnesium sulphate one-half ounce every morning. 14. De-leading should not be done continuously for more than four days at a time and only once a month. 15. Six to fifteen courses of de-leading may be necessary. It may never be complete but symptoms are permanently controlled and the period of disability reduced by half. 16. Symptom free "in-susceptibles" may have large quantities of lead stored in bone ready to be liberated by artificial or spontaneous de-leading. Clinical symptoms are essential in diagnosis. Toxic symptoms do not necessarily parallel absorption and excretion rates. 17. The toxic dose of lead is only one to two mg. daily if continuous over a period of several years. 18. Lead is absorbed mainly by inhalation, less by ingestion, very little by absorption through the skin, except in special form such as tetra-ethyl-lead. 19. Prophylactically in lead industries air analysis for lead dust may be made and respirators used when necessary. Reticulocytosis is one of the earliest signs. Stippled cells are regarded as one form of reticulocytes. An intravenous lead injection may cause as high as 30% reticulocytosis and a transient polycythemia. 20. Lead in the urine in excess of .2 mg. in a 24 hour specimen is a danger signal. The modern industrial physician aims to keep it well under .1 mg. per day. 21. Interval examinations of blood and urine in lead workers are of great value in controlling clinical lead poisoning and illustrate the principle of periodic health examination in industry.

## SECTION VI—*Abdominal Surgery*

### Factors Pertinent to the Reduction of the Mortality in Cholecystectomy\*

By

MOSES BEHREND, M.D., F.A.C.S.  
PHILADELPHIA, PENNSYLVANIA

THE chief factor, concerning the reduction of the morbidity and mortality following the operation of cholecystectomy is the acquisition of an intimate knowledge of the anatomy of the bile passageways. The best way to obtain this knowledge is the study of anatomical specimens gained from dissections and animal experimentation. Nothing can supersede the intimate knowledge derived from personal dissections in the anatomical laboratory.

While teaching anatomy in the Baugh Institute of the Jefferson Medical College, it was my privilege to observe the anatomical relations of the bile ducts and blood vessels in about 400 cadavers. In these, it was demonstrated that while normal relations were observed in 75% of bodies examined, there were 25% of anomalies; these anomalies undoubtedly account for many mistaken identifications occurring during operation. However, these alone are not responsible for the sole errors in technic, because even where we have normal relationships of the bile passageways, our errors are frequently those of commission, as well as of omission.

Is there a way to avoid these errors in technic? If we never fail to incise the right free border of the gastro-hepatic omentum, the cystic and common ducts are uncovered, which immediately allows us to see the relationship of the cystic duct to the ampulla of the gall bladder. The gall bladder should never be removed unless this relationship of the cystic duct entering the ampulla of the gall bladder is observed. The cystic duct should never be clamped within its peritoneal coat, but instead the "open" operation should be performed. I still observe too many surgeons performing the operation of cholecystectomy within the folds of peritoneum hiding the cystic and common ducts. By means of the "open" operation the common duct ought never be in danger of being incised, ligated or destroyed. And this applies as well in those cases where the peritoneum, covering the ducts, as a result of inflammation is much thickened and indurated, thus resulting in a sort of homogeneous mass at the site of operation. In these cases it is also important to incise the thickened peritoneum with a knife and then, by blunt dissection with a long curved scissors, the

cystic and common ducts reveal themselves to the full view of the surgeon.

#### SPINAL ANESTHESIA

There is no question in my mind about the efficacy of spinal anesthesia to reduce the mortality and morbidity in operations on bile passage-ways. The ease with which operations can be performed under "spinal" undoubtedly saves lives. For one thing the liver is not traumatized; this I believe has been one of the causes of so-called "liver deaths." Great care, however, must be exercised, that on account of the resultant relaxation, the common duct be not mistaken for the cystic duct and thereby destroyed or injured. Precaution as outlined in the previous paragraph will obviate the great majority of accidents.

#### GLUCOSE

The administration of glucose by veneclisis and hypodermoclysis before operation has the beneficial effect of making the liver more tolerant to traumatism. The maintenance of the glycogen reserve is important in all operations on liver and bile passageways. Glucose is given usually on three successive days before operation in doses of 500 cc. of 5% strength when given under the skin and by proctoclysis and 10% when given into the vein. An important article has just been published by Cutting on this subject. He states that a 5% solution is isotonic and is readily absorbed by the bowel. It was always my impression that dextrose was absorbed through the intestinal tract. This was proven to my satisfaction in a case where a cholecystostomy had been performed. While proctoclysis was being given, large quantities of the fluid were excreted through the fistulous opening. The objection to proctoclysis as I see it, is the lack of co-operation one gets on the part of the patient in retaining the fluid. It seems, however, in some cases no matter what procedure is employed, patients cannot retain the fluid given by proctoclysis, so that this method practically has been abandoned now for the introduction of fluids by veneclisis and hypodermoclysis.

#### ACUTE CHOLELITHIASIS, ACUTE CHOLECYSTITIS, ACUTE EMPYEMA

At present a wave of enthusiasm is permeating the profession concerning the emergency treatment by operation of these acute cases. I want to sound a note of warning against such a procedure. For many years I have maintained that acute cases should not be oper-

\*Read before the Post-Graduate Medical Assembly, Geisinger Memorial Hospital, November 1, 1934.  
Submitted March 25, 1935.

ated on immediately because the dangers of operation are greater than when symptoms have been allowed to subside. Fine dissections cannot be made on hard, turgid gall bladders and their surroundings; isolation of the ducts becomes practically impossible; the danger of spilling pus is always imminent; rapid lymphatic, generalized infection results if the gall bladder is removed. If not removed then an incomplete operation is the result. Only a few days ago, a patient who had been operated on in another hospital for acute empyema presented herself. She stated that she was "terribly sick" following the operation and was not expected to live. Her gall bladder had been drained. I removed the gall bladder which was filled with stones the size of walnuts. By allowing the inflammation to subside however, operations on acutely ill patients can always be completed; on the other hand, with the conditions reversed, it becomes necessary frequently to perform the unanatomical operation, namely that of removing the gall bladder from above downward. Such a procedure may lead to considerable oozing which masks the field of operation and thus may lead to unforeseen technical errors.

### PERFORATION

Perforation about which we read so much at present can be avoided, or at least greatly lessened, in acute cases, if we take away absolutely all food and liquids. I have never failed to see a subsidence of acute symptoms, if the patient were hospitalized. To illustrate. A patient was seen by me in consultation last week. He had been given liquids by mouth; in the presence of intense pain in the right hypochondriac region. His temperature was 102° F. A huge gall bladder easily could be outlined. He was admitted to the Jewish Hospital in the evening when the strict regime just mentioned was begun. The following morning with veneclysis, hypodermoclysis and absolute abstinence of food or drink by mouth, the temperature had dropped almost to normal, the pulse followed; tenderness and rigidity had markedly subsided. Within a few days the patient will be ready for operation. With due respect to the internist, I believe the only way to treat these acute cases is to put them under the absolute care of the surgeon and hospitalize them. Daily consultation with the internist for these seriously sick patients is encouraged.

### THE COMMON DUCT

The advice given by Lahey that practically all common ducts should be opened and examined for stones will lead to increased mortality. The "occasional" surgeon is not sufficiently experienced in operating on common ducts. No surgery is more difficult than this type of work. Much can be learned from the history. If in addition it reveals the presence of jaundice at any time, the common duct should be explored. Much information can be obtained from palpation of the common duct.

### DRAINAGE

Drainage after operation on the gall bladder is rarely used now; exceptions are those cases where there is considerable oozing, or when there has been leakage from the ducts. The omission of drainage after operations reduces mortality because the occurrence of subhepatic and subphrenic collections has been

eliminated. Never have we been compelled to open a case where no drainage was employed. On the other hand, on several occasions when drainage was used, after the drain was removed and the wound had healed, operations had to be performed for secondary collections.

### JAUNDICE

The mortality can be greatly reduced if we do not perform cholecystectomy in the presence of jaundice. Jaundice complicates the operation because of the uncontrollable oozing that occurs in a certain number of cases. For the control of such bleeding nothing is better than blood transfusions. For several years I have discontinued the use of calcium before and after operation in jaundiced patients.

### REPORT OF DEATHS

Since my last published paper (1) on this subject I have had two deaths, the first in 34 months. One case, a woman, was admitted to the Jewish Hospital on the Medical Service for acute empyema of the gall bladder. She had a shattered heart with the presence of fibrillation. Repeated consultations were held between the internist and the surgeon. She remained on Medical Service for three weeks before being operated on. She was thoroughly prepared by means of glucose; cardiac support was given before and after operation. She died one week after operation.

The other case was also that of a woman about 45 years of age, admitted to the Mt. Sinai Hospital, with severe upper abdominal pain. On physical examination the entire right side was rigid and tender. Blood urea nitrogen was 84, which dropped to 15 in about 10 days. She was then operated upon. While the blood urea nitrogen was high she was confused, depressed and could not answer questions intelligently. The gall bladder, filled with stones, was removed. She died of a massive atelectasis.

These patients did not die as a result of technical errors, but rather from an unforeseen complication in the last case and from a not unexpected complication in the first case, because of the fibrillation before operation. The low mortality does not mean an evasion of cases that were poor risks. This applies to those cases also that were admitted to the Philadelphia General Hospital; the physical conditions of these patients is not the most desirable for serious operations. Cases of carcinoma of the bile passageways are not considered in the estimation of mortality.

The mortality also can be reduced by removing the gall bladder within its peritoneal fold. In this manner the bed of the gall bladder is not lacerated. It has been shown that deaths have occurred from the rapid absorption of inflammatory products through the lymph channels. Most of us are familiar with Dr. Max Thorek's technic. He leaves the posterior wall of the gall bladder attached to the liver and fulgurates it before suturing the edges of the liver. He believes that in this way he avoids death because of the sealing of the lymphatics. In a paper read before the American Congress of Physical Therapy held in Philadelphia recently, he reported 90 cases so operated upon without a death.

### CONCLUSIONS

There are certain axioms in gall bladder surgery which if adhered to, will in my opinion, reduce the mortality.

These are:

1. An intimate knowledge of the common and special anatomy of the bile passage-ways.
2. Spinal anesthesia because of the relaxation it affords, has greatly reduced the mortality.
3. Glucose and blood transfusions before and after operations are of great value.
4. Do not operate as an emergency on acute cases.
5. Put the stomach and intestinal tract at absolute rest.

6. Do not explore the common duct unless there is some very good reason.
7. The less we institute drainage, at operation, the better.
8. Never perform a cholecystectomy in the presence of jaundice.
9. Whenever possible remove the gall bladder within its peritoneal fold.

## ABSTRACTS

BOLAND, FRANK K.

"The Interpretation of Abdominal Pain." *South Med. Journ.*, 28:133-138, Feb., 1935.

Pain is generally the chief guide to the surgeon that he is dealing with a surgical condition in the abdomen. Errors in diagnosis result principally from lack of knowledge and lack of care, especially the latter. Symptoms referred to the digestive tract are attributed to (1) close anatomical relationship with contiguous structures for example, kidney, ureter, or diaphragmatic pleura; (2) influences traveling through the blood stream, as certain allergic conditions, acute diseases as measles, lead poisoning, undulant and rheumatic fevers, malaria, and arachnidism; and (3) factors dependent upon the nervous system—the digestive tract being unique in that it has both sympathetic and parasympathetic fibers. Conditions to be considered under the general heading of this last group include pneumonia, psychoses, the gastric crises of tabes, herpes zoster, cord tumors, vertebral disease, and sequellae of phrenic nerve operations. Head's law of referred pain is quoted and explained. In discussing the differentiation between cardiac and gall-bladder disease he quotes Vest's statement that "the rank and file of the profession realize neither the significance of the relationship nor the necessity for thorough study and evaluation of both organs when either presents symptoms".

The article is closed by the summarization of several cases illustrating some of the conditions mentioned previously in the paper.

J. Duffy Hancock, Louisville.

D'ABREU, A. L.

*Surgical Aspects of the Spastic Colon and the Prediverticular State.* *Lancet*, 227, Dec. 22, 1934 1385-88.

This paper deals with that group of patients sometimes suffering from left-sided abdominal pain, blood and mucus in the stool and diarrhoea. They are frequently diagnosed vaguely as "colitis".

The commonest patient of this type is the fat middle-aged muscular man, athletic in his younger days. X-ray is indecisive, areas suggestive of the prediverticular state which Spriggs and Marxer have described as "a ragged outline of the bowel which does not dilate even in the most favorable position" and in which normal segmentation is lost, may be seen.

Laparotomy when performed under spinal anaesthetic reveals a definite pathology. Reddened areas of the colon are seen which from time to time pass into severe spasm. Such pathology is not seen if general anaesthesia

is used for then the parasympathetic impulses necessary for this peristaltic action are lost. In portions of the bowel in the prediverticular state removed along with areas of established diverticulation the most notable change seen is hypertrophy of the circular muscle coat which projects as bands into the lumen of the bowel.

What causes this hypertrophy? There is some evidence to support the theory of parasympathetic overaction. Deficiency of the parasympathetic nerves has been shown in cases of megacolon. Megacolon has been experimentally produced by cutting the parasympathetic nerves to the colon in cats. Vagatonics show hyperchlorhydria, pylorospasm and spastic colon.

In conclusion, it is seen that, in many cases of colon dysfunction, spasm and overactivity of the circular muscle of the bowel play an important part and are factors of the greatest importance in the development of diverticula. The cause of this may be parasympathetic overactivity.

John J. Day, Montreal.

EBELING, W. W., M.D.

*Absorption of Dextrose from the Colon.* *Arch. Surg.*, Vol. 29, No. 6, Dec., 1934, pp. 1039-1047.

This article is a report of a series of experiments done on a chronic colon loop to determine the absorption of dextrose from the colon.

From these experiments, it was shown that the ratio of absorption of dextrose from the colon increased slightly with increasing concentrations up to 5 per cent, which approximates an isotonic solution. With increasing concentrations beyond this point, there was a decided increase in the rate of dextrose absorbed. It was further shown that with an increase in the volume of the solution, concentration remaining constant, there was a decided increase in the amount of dextrose absorbed.

A comparison of the results found in this group of experiments as compared with a previous group, showed that anesthesia per se made little difference in the conduct of the colon as a physiologic unit.

It was also shown by comparing these results with a previous series done by Ravdin on absorption from the ileum or jejunum.

The author feels that as the result of his experiments, the colon as a means of introduction of dextrose into the body mechanism is inadequate for clinical needs and further actual harm may result in the use of hypertonic solutions owing to the large withdrawal of water.

N. W. Swinton, Boston.

## SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### ADVERTISEMENTS SHOULD BE READ

THE opening of an elaborate and important new research laboratory by one of the world's leading manufacturers of biologicals and pharmaceuticals, re-emphasizes the degree to which the modern producer of therapeutic agents has become the "post-graduate" or the "continuation" avenue through which investigations initiated in educational institutions are carried to practicality, and thence to physicians.

Sera, bacterins, glandular derivatives, germacids, cardiovascular-renal medicines, vitamin-rich substances, foods devised for special purposes, roentgenological and actinological apparatus—and a host of other aids to the diagnosis, prevention and treatment of disease—all are made available in our professional practice because forward-looking, approachable and soundly established concerns are alert to recognize new trends, to new methods, to welcome original, promising ideas. Even though physicians not rarely find it difficult to keep abreast of unique therapeutic principles and preparations and even though, at times, they believe that products are distributed before their specific worth altogether has been proved, yet none denies that our profession would be in a sad way, from the diagnostic and treatment angles, were not a conscientious, hard-working group composed of both scientists and business men constantly striving to progress and to improve.

So generally distributed are our industrial chemists (pharmaceutical manufacturers) and our industrial mechanics (apparatus makers) and so dependable are their products, that, perhaps, we are too apt to take them for granted, failing to realize not alone the tremendous capital needed to keep going these enterprises but also the very essential service which they contribute to the physician's management of the ill or to humanity in general.

It would seem but proper that occasionally, when we open a package of a medicinal or biological preparation which, with all confidence, we may employ and by whose exhibition we improve our standing as physicians, we give thought to what steps already have been taken, and *by how many people*, before that particular agent reaches our hands. Those steps constitute a modern romance: the collection of the potent substance "in the raw," the discovery of its usefulness, the multitudinous processes necessary to prove actual values, the contact with those who are willing to risk capital on advanced research or mass production (for often indeed consideration of substances or ideas proposed during a decade will show that great sums are expended upon what eventually proves unworthy or impracticable), the intricacies of manufacture, the handling and packaging, the distribution and sale. It is a long, long trail which has been trodden before the physician has before him in a syringe, a powder, liquid or tablet the therapeutic agent whose

possibilities were appreciated by some keen mind, whose "mother substance" was snatched from the humid, fever-ridden marshes bordering the oozy African Congo or sliced from a yet quivering carcass amid the sickening scenes and confusion of a huge abattoir.

The patient "detail man" may bring before the doctor what is "new" in therapy but commonly, notice of these modern miracles reach him *via* the advertising pages of the medical journals.

*And he should read these advertisements!* For today, they are not constituted of the medicine wagon lingo of our early memories. Through them, firms tell truths, simply, efficiently and tersely—not alone because actually they wish to inform physicians but because no professional critic of their announcements is so scrutinizingly relentless as are those of their own craft. By whatever criteria their products may be classed by "boards" or "councils," no check upon loose or careless claims, boasts and exaggerations or composition or methods of manufacture approaches in severity that of concerns engaged in like enterprises. It is their *competitors*, not medical organizations or individual doctors, who classify firms and their ads as "right" or "off color."

*Medical publications depend largely for their existences upon advertising revenue.* This Journal has sought to protect its advertisers, by seeing to it that they are kept in "right" company. By so doing, also, it has protected its readers from the intrusion upon their time and ethics, and from insulting their scientific training and experience: complications sure to follow by the admission to its advertising pages of the swarm of "twilight zone" firms which swoops down upon every legitimate medical publication. If such firms can get into the company of "right" advertisers, they conclude that physicians will accept the stuff which they announce as "right." This policy of "selective exclusion" has proved very costly to this magazine's publishers, but they are convinced that it is appreciated, both by our advertisers and our readers. The policy will be maintained. The advertising pages must be kept in tune with the high order of the Journal's scientific text.

Finally, there is no question that readers owe great debts of gratitude to firms and institutions who maintain the highest possible standards of scientific manufacturing and ethics and whose ideals rise above mere dollar-making. Particularly should our readers be appreciative of those firms whose commercial announcements are printed in this publication, and which permit the publishers to issue this Journal in its present size and its unusually attractive format. Whenever possible, readers should go out of their way to use or to recommend the excellent products which our advertisers submit. They announce the best; the best should be none too good for patients and for office and hospital exhibition.

F. S.

## ABANDONING FREE REPRINTS

**I**N the attempted economic "comeback," one of the Administration's pet projects has been the raising of prices. Far be it from us to question the wisdom or the necessity of such course. We leave decisions of this kind to those at present in authority.

While the general increase in costs to the public may put into circulation greater amounts of money and this manoeuvre may enable manufacturers to pay higher wages and retailers to secure greater dollar-profits, yet, it cannot be denied that, in the workings of the mechanism whereby prices to the consumer are raised, certain groups suffer.

One of the classes upon whom is imposed an onerous burden, is the magazine publisher—particularly, he who issues a scientific publication. Verily, he is "between the devil and the deep sea": he finds it impossible to raise his annual subscription-rate or the charges which he makes to his advertisers, yet his publishing costs—paper, illustrations, labor, printing—all step up briskly. As a consequence, he is compelled to "cut corners" in every conceivable fashion.

This Journal has been affected as have others. It has endeavored in no way to "economize" through cheapening its product. Its paper, style, make up, printing of elaborate tables, graphs, photographic reproductions—all have remained uncurtailed. But the management no longer is able to supply authors with the customary fifty *gratis* reprints.

Of course, many of our leading medical journals never have granted free reprints and do not do so at

present. However it had been the desire of this Journal to make at least a gesture of appreciation of the efforts of its contributors and present them with reprints sufficient to enable them to circulate the results of their studies among interested friends and colleagues. That the Journal no longer is able to help this laudable purpose assumes the significance of a major sorrow. We trust that our contributors will understand our regret and will appreciate our position.

Parenthetically, it may be mentioned that the issuance of reprints—paid for or *gratis*—imposes a considerable burden upon magazine publishers. In pride at seeing his work in type and in the exuberance consequent upon a job well-done, not rarely an author orders great numbers of reprints. His intentions are entirely understandable to publishers. However, by the time the publisher furnishes the reprints, not uncommonly, the contributor has become engrossed with other tasks to a degree where his check-writing arm has become weakened or wholly inert: as a result, this and other publications, each month lose hundreds of dollars because contributors fail to remember to remit for reprints supplied to them at cost. When they do not pay, the publisher has to foot the bill!

We shall appreciate all possible help in solving this reprint problem. Our contributors can depend upon the publishers again furnishing a number of reprints *gratis* just so soon as economic conditions make such course possible.

F. S.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

★★★★ *"Physiology in Modern Medicine,"* J. J. R. Macleod, M.B., LL.D., D.Sc., F.R.C.P., F.R.S., Regius Professor of Physiology in the University of Aberdeen, Scotland, etc., with the collaboration of Philip Bard, Edward P. Carter, J. M. D. Olmsted, J. M. Peterson, and N. B. Taylor; published by the C. V. Mosby Company, St. Louis, Mo., 1935.

This substantial, inclusive, and inspiring volume of 1154 pages is the seventh edition of a textbook which has enjoyed great popularity since the first edition appeared in 1918. The word "biochemistry" has been removed from the title, and chemical subject-matter has been included "only so far as is necessary to the elucidation of the problems of animal function."

The work of the five collaborators has made it possible to give the work a completeness and up-to-date-ness which would be impossible for one man to attain, in this day and age. The final editing has been so smoothly done that there is no suggestion of the incoherence and repetition which occasionally mar such work. There are 297 figures, 7 of them in color. The table of contents and the index are both good, and the bibliography deserves the highest commendation.

Going through the table of contents, your reviewer was surprised by the absence of a section on reproduction. A few years ago it was customary to lament the fact that the chief source of information on this subject available to most people was gossip and popular jests. At present the situation is not so much better as one might expect. Suppose that one wishes to know whether a given troublesome symptom in a woman may be a normal incident to her menopause, or that one wishes to refer an intelligent patient to a book in which she will find a description of what to expect during this worrisome period. If one goes to the textbook of gynecology that is most popular among students here at present, one finds, not a connected account of the normal menopause, but scattered items amid a mass of pathological and surgical discussion. Suppose that one wishes to know whether in this climate it is normal for a boy of 12 to have erotic dreams with emissions. If one goes to the two textbooks of urology most popular here at present, one discovers that the first does not even contain the word "puberty" in its index; the other book has it, but is so filled with misleading, antiquated verbiage about "solitary vice" and "involuntary pollution" that it reads like something out of the nineteenth century. If one goes to a

textbook of psychology one may find a pitiful, shrinking nucleus of normal facts so surrounded by a spongioplasm of the speculative and the abnormal that layman and physician alike are repelled.

Surely, then, the physiologist must assume more responsibility than merely "to ascertain to what extent the known laws of physics and chemistry explain the phenomena of life." He has the further responsibility,—indeed, it might be considered his *first* responsibility—of describing and defining, for the clinician and his patients, the normal function of everything in the body. We should be able to go to him for concrete, even quantitative, statements as to the physical details of the normal human life.

The extent to which physiologists have evaded this responsibility in the past is amazing. One very well-known book of 862 pages has a section of 1¼ pages headed "Reproduction," in which the author mentions Shakespeare and Sir Thomas Browne, refers literally to the lilies of the field, and finally, gathering up all his courage, devotes the remaining half-page to parthenogenesis in the sea-urchin. In many books some of the subject-matter in question may be found under "Endocrinology," with the questions which are most urgent to the average reader left unanswered.

It seems unkind to report this defect in a book which in every other respect is magnificent. It will be found useful alike to the student, the instructor, and the medical practitioner.

Frederic T. Jung, Chicago.

"Emotions and Bodily Changes," by H. Flanders Dunbar, M.D., Ph.D., Columbia University Press, New York, N. Y., p. 595, \$5.00.

**T**HIS survey of literature on psychosomatic interrelationships covers the involved problems without omission of important contributions and without confusion of theory with fact. The integration of soma and psyche as but different manifestations of the person, develops the organismal view-point. The average 'medically trained mind' may require some reconditioning prior to acceptance of the connotation of this philosophico-physiologic trend—namely, the saturation of the tissues with soul. 'Soul' being closely related with 'purpose,' the individual cannot be intelli-

gently perceived save within a broad focus which includes his multiform and manifold relationships with environment. Equally unintelligible becomes an organ separated from its functional life or a tissue dissected from its organ. Since, up to the present, the analytic attitude and method have brought us to an obvious *impasse*, the newer method of 'wholeness' or integration may build a new structure of facts upon the fundamental theorem that the whole is more than the sum of all its parts. Psychosomatic dichotomy appears to be yielding to psychosomatic unity.

The large section on organs or organ-systems presents almost endless evidence of the primary importance of psyche in the production of somatic symptoms, as well as the reverse. This material is, of course, all very much up-to-the-minute in scope and accuracy. The subsection on the digestive tract is well handled and many outstanding gastroenterologists are extensively quoted, both American and foreign.

Dr. Dunbar's book is interesting, stimulating and practical. To medicine it brings a specific and very practical message. To psychology and psychiatry it offers much valuable correlation with the soma. In biology and philosophy the book is of monumental importance. More than 120 pages of bibliography are added for those who desire to pursue the subject further.

The integration of soma and psyche is a brave and ponderous labor projecting itself doubtless into the next few centuries. The new synthesis demanded by the current and modern intelligence in its (usually inadequate) attempt to adjust to the immensities, might grow from this root-stalk of psychosomatic integration. The purpose of the individual human has so far only the religious and philosophic explanations available, especially in so far as the psychic phase is concerned. Successfully demonstrated integration of mind and body could scarcely fail to lead to several potentially important consequences anon—a form of pantheism built on knowledge rather than faith, conservation of the energy units of psyche as well as the conservation of the energy units of organized matter. Dr. Dunbar has done much to lessen chaos within this difficult and fascinating terrain.

Beaumont S. Cornell, M.D., F.A.C.P.

## SECTION X—After “Hours”

### An Exhibition of Books Illustrating the Progress of Gastroenterology Shown at the Graduate Fortnight\*

OCTOBER 22—NOVEMBER 2, 1934

Arranged by

BURRILL B. CROHN, M.D.

and

B. D. ROSENAK, M.D.  
NEW YORK CITY, NEW YORK

**P**HYSICAL limitations of space necessitate the omission of many valuable and essential links in the history of the development of this subject. The purpose of this exhibit was to demonstrate the outstanding publications rather than to give an exhaustive display of all works. We wish to thank the Library Staff for their kind assistance in preparing the exhibition.

#### HYGIENE AND MEDICINE IN ANTIQUITY

##### BIBLE.

The Holy Bible, Conteyning the Old Testament and the New . . .

London, by Rob. Barker, 1611.

First issue of the first edition of the authorized version.

Opened at Chapter XI of Leviticus, to show dietary laws and sanitary regulations.

Kindly lent by the Union Theological Seminary.

##### JASTROW, MORRIS (1861-1921).

The Liver in Antiquity and the Beginnings of Anatomy.

In: Tr. Coll. Physicians of Phila. 3. ser. 29 :117-138, 1907.

Anatomy began in antiquity with the study of this organ, regarded at that time as the seat of the soul and of life. It was the organ most carefully scrutinized as a means of divining the future, of exorcizing evil, and of forestalling misfortune.

Opened at p. 126. Excellent clay models of the liver exist dating back as far as 2000 B.C. (Babylonian period of Hammurabi). The lobes of the liver were studied and the position of the fissures and of the gall bladder noted.

##### HIPPOCRATES (*b. ca. 460 B. C.*).

Cinquieme livre des epidemies. In his: Oeuvres completes . . . Traduction nouvelle . . . par E. Littré.

Paris, Bailliere, 1839-1861, vol. 5, pp. 198-259.

Opened at pp. 206-207. Case 6 is probably a clinical description of a gastric or duodenal ulcer with a spontaneous remission or healing. This short clinical note is a characteristic example of the ability of the first great physician to observe, to correlate and succinctly to describe.

##### GALEN (*ca. 129-200*).

De Naturalibus Facultatibus . . . In his: Opera ex Nona Juntarum Editione . . .

Venetis, apud Juntas, 1625, vol. 1, ff. 289/90-308.

Galen is the outstanding representative of Roman medicine or rather of Greek medicine in Rome. He was an ardent admirer of Hippocrates, but scoffed at the Alexandrians and subsequent schools. His was the dominant influence throughout mediaeval and monastic medicine.

Book III, p. 303 is an excellent example of Galen's knowledge of a gastro-intestinal subject. He is lacking in the underlying understanding of anatomy and physiology, yet he is practical, logical and reasonable in his handling of the subject.

On the Natural Faculties, with an English Translation by Arthur John Brock.

London, Heinemann, 1916.

Opened at p. 237: "Thus the two faculties are clearly to be seen in the case of the uterus; in the case of the stomach they appear as follows:—Firstly in the condition of gurgling, which physicians are persuaded, and with reason, to be a symptom of weakness of the stomach; for sometimes when the very smallest quantity of food has been ingested this does not occur, owing to the fact that the stomach is contracting accurately upon the food and constricting it at every point; sometimes when the stomach is full the gurglings yet make themselves heard as though it were empty. For if it be in a natural condition, employing its contractile faculty in the ordinary way, then, even if its contents be very small, it grasps the whole of them and does not leave any empty space. When it is weak, however, being unable to lay hold of its contents accurately, it produces a certain amount of vacant space, and allows the liquid contents to flow about in different directions in accordance with its changes of shape, and so to produce gurglings."

##### EARLY CLINICAL MEDICINE AND RENAISSANCE ANATOMISTS ARETAEUS (*Cappadox*) (*Second to third century, A. D.*)

On the Causes and Symptoms of Chronic Diseases. In his: Extant works . . . edited and translated by Francis Adams.

London, Sydenham Society, 1856, Book II, pp. 291-373.

Little is known of the life of Aretaeus. He was a contemporary of Galen, but it is only in more modern times

\*Published through the courtesy of the Officers and Committees of the New York Academy of Medicine. Only a partial list is published herewith.  
Submitted February 12, 1935.

that he has been appreciated as the clinician of his period ranking next to Hippocrates.

Opened at p. 353, at section on dysentery, remarkable in its perfect description of the clinical features and pathological picture of instances of ulcerative colitis or dysentery. It is quite obvious that Aretaeus dissected his post-mortem material.

AVICENNA (980-1037).

Canon de Medicina. Lib. I-V. Translated by Gerardus Cremonensis.

Venice, Petrus Maufer et socii, 1486.

The translations which follow are taken from: Gruner, O. C. A Treatise on the Canon of Medicine of Avicenna. London, Luzac, 1930.

"The standard *size of the meal* depends on usage and vigor. A normally robust person should take as much as will not produce a sense of heaviness, or a sense of tightness of the hypochondria. There should be no subsequent rumbling in the stomach, or splashing of the food on bodily movement. Nausea should not be experienced, nor a canine appetite, nor loss of appetite, nor great disinclination for exertion, nor sleeplessness. The taste of the food should not repeat in the eructations. If the taste of the food lingers in the mouth a very long time after the meal, it shows that the latter was too heavy.

"A person who cannot digest the amount of food appropriate for him should increase the number of articles of diet, but diminish the quantity.

"A person of atrabilious constitution needs a diet which is very humectant but not very heating.

"A person of choleric constitution needs a diet which is humectant and infrigidant.

"A person who generates hot inflammable blood needs feebly nutritious articles of food, which are cold. One who generates phlegmatic blood needs feebly nutritious articles of diet which are hot and attenuant."

MUNDINUS (ca. 1275-1350).

Anatomia. Edited by Martinus Pollich de Mellerstat.

[Leipzig, Martin Landsberg, ca. 1493].

Mundinus, the son of an apothecary, was born in Bologna. The mediaeval revival of human dissecting centers around him. This little treatise of systematic anatomy based on the dissection of autopsy material was the most important anatomical work in the medical schools until superseded by Vesalius' *Fabrica*.

Opened at f. Biv to show sections dealing with the anatomy of the duodenum, mesentery and stomach. A translation of this portion follows. "And it is said that the first intestine is called the duodenum because its length generally is twelve fingers. And a certain intestinal duct from the gall bladder joins this, and for that reason be careful when you dissect not to cut this duct: but cut the intestine well below the duodenum and ligate it and then begin as classical authors began. You have six intestines. The first is the duodenum, the second the jejunum, the third the ileum, and these are slender and placed superficially. The fourth is the caecum, the fifth is the colon and the sixth is the rectum. All these intestines you will see to be rolled up and continuous and attached dorsally, just as all viscera are attached by a certain part which is called *encaras* or rather the mesentery from the mesenteric [veins] which are in it, and the Bolognese call it colloquially the *interium* as it holds up the intestines."

DA VINCI, LEONARDO (1452-1518).

I Manoscritti . . .

Torino, Roux e Viarengo, 1901. Fogli B, Dell'anatomia.

The greatest artist and scientist of the Italian Renaissance. He made over fifty careful and accurate human dissections, years before Vesalius, and drew the muscles and skeleton with great accuracy. He was also interested in the thoracic and abdominal viscera.

Opened to plate preceding p. 99.

This illustration of the thoracic and abdominal cavity shows the oesophagus as a straight tube joining the mouth cavity and the stomach. The intestinal coils he represents in several different forms, but fails to recognize the constant curve of the duodenum. The colon is fairly accurately represented and the appendix is shown.

The notes are in "mirror writing."

VESALIUS, ANDREAS (1514-1564).

De Humani Corporis Fabrica Libri Septem.

Basileae, ex off. J. Oporini, 1543.

This masterpiece of Vesalius was the culmination of many years of dissection and teaching of anatomy. It is divided into seven books and is beautifully illustrated by Jan Kalkar, a pupil of Titian. It has never been completely translated. Vesalius has been called "The Reformer of Anatomy" and his book completely disposed of Galenical anatomy.

Opened at p. 365.

Book V is devoted to the abdominal viscera. The omentum and the general disposition of large and small bowel are illustrated and described. The vermiform appendix is portrayed, and described in the text. The "mesenteric gland" or pancreas is described, but the stomach, liver, spleen and kidneys are inadequately portrayed.

#### 17TH CENTURY ANATOMISTS

ASELLIUS, GASPARD (1581-1626).

De Lactibus . . .

Mediolani, apud J. B. Bidellum, 1627.

One of the post-Vesalian anatomists, Aselli was the first to oppose the Galenic idea that chyle passed directly through the mesenteric veins to the liver. It is said by some that he did not actually see the lacteals, merely inferring their existence. He nevertheless expounded strongly on this subject and subsequent anatomists substantiated his teaching.

His original striking colored woodcuts constitute the first use of this medium in anatomical illustration.

GLISSON, FRANCIS (1597-1677).

Anatomia Hepatis.

Londini, typ. Du-Gardianis, 1654.

Famed as anatomist, physiologist and pathologist. His most important contribution was an accurate *description of the capsule of the liver as well as of its blood supply*. He was a graduate of Cambridge and was for many years Professor of Physic at his Alma Mater. He was one of the founders of the Royal Society.

Opened at pp. 146-147: description of bile duct.

WIRSUNG, JOHANN GEORG (d. 1643).

Figura ductus cuiusdam cum multiplicibus suis ramulis nouiter in Pancreate . . . in diuersis corporibus humanis obseruati.

Paduae, 1642.

Wirsung, a prosector in anatomy at Padua during Vesling's time, discovered and described the pancreatic duct. The original plate showing this study is exceedingly rare, having been published as a single small oblong folio. Vesling incorporated this fact in his subsequent editions, giving the credit to Wirsung for the discovery. The plate shown was that reproduced in Ludwig Choulant's *History and Bibliography of Anatomic Illustration*, Chicago, Chicago University Press, [1920], p. 244.

WHARTON, THOMAS (1614-1673).

Adenographia, sive Glandularum Totius Corporis Descriptio . . .

Londini, J. G. imp. authoris, 1656.

One of a great group of 17th century anatomists. In this book, the first edition of which is shown, the various glands are described in greater detail than by previous authors.

Opened at pp. 132-133, to show illustration of duct of submaxillary gland.

STENON, NICOLAUS (STENSEN, NIELS) (1638-1686).

Observationes Anatomicae.

Lugd. Batav., P. de Graaf, 1680.

A priest and physician and an accomplished man in many fields: anatomy, physiology, geology and religion. In 1661 he discovered the duct of the parotid gland in the sheep and this discovery was published in his *Observationes anatomicae* in Leyden in 1662.

Opened to show illustrations opposite p. 37, of the duct of the parotid gland in sheep.

HENLE, FRIEDERICH GUSTAV JACOB (1809-1885).

Symbole ad Anatomiam Villorum Intestinalium. . .

Berolini, A. Hirschwald, 1837.

One of the greatest histologists of his time and one of the most eminent contributors to anatomy of all time. His outstanding contribution to gastroenterology was the accurate description of the epithelium of the intestines and identification of the intestinal villi. The lymph vessels of the villi were recognized and their communication with the blood vessels of the mesentery was noted.

Opened at p. 37, to explanation of illustrations of epithelium of intestines. Illustration unfolded for view.

#### CHEMICAL PHYSIOLOGY

VAN HELMONT, JOANNES BAPTISTA (1577-1644).

Ortus Medicinæ. . .

Amsterdam, apud L. Elzevirium, 1648.

A disciple of Paracelsus, van Helmont maintained the idea of "archaeus," the guiding spirit of all material processes. He observed the production of "gas" in the numerous chemical processes characteristic of "fermentations." This gas was a spirit liberated from various substances by the action of fermentation. Gastric digestion began in the stomach as a "fermentation" process which turned food into chyle. Further fermentation or chemical change occurred in the intestinal tract and transformed chyle into "crude blood," thence to the liver as "vital blood" and returned to the heart as the vital spirit or "archaeus."

Opened at pp. 202-203.

van Helmont considered gastric juice to be "acid."

DE GRAAF, REINIER (1641-1673).

De Succo Pancreatico. In his: Opera Omnia.

Lugd. Batav., Ex officina Hackiana, 1677, pp. 491-566.

de Graaf was a pupil of Franciscus Sylvius, and at the age of 23 made an investigation of the pancreatic juice, first published in Leyden in 1664. Using a quill as a cannula he examined the secretions of the pancreatic duct in a dog and determined, chiefly by taste, that the juice was "acid." He thought that bile and pancreatic juice mixed and effervesced in the duodenum.

Opened at p. 505: chapter on pancreatic juice. This is the first attempt at experimental physiology in medical literature.

DE REAUMUR, RENE ANTOINE FERCHAULT (1683-1757).

Sur la digestion des oiseaux.

In: Mem. Acad. ray. d. sc., pp. 266-495, 1752.

The investigations of Reaumur were extremely diverse. He was the author of a great work on insects, and was the inventor of the thermometer which bears his name.

In his work on the digestion of birds he utilized the well-known habit of kites of rejecting particles which they could not digest and fed them wire mesh capsules in which portions of food were placed. He studied the solvent action of the gastric juice on these rejected foods and calculated that "putrefaction played no part in gastric digestion," thus refuting van Helmont and Sylvius.

YOUNG, JOHN RICHARDSON (1782-1804).

An experimental Inquiry into the Principles of Nutrition and the Digestive Process.

[Phila., T. & W. Bradford, 1805.]

This study was the graduating thesis of the young student at the University of Pennsylvania. In it he demonstrated that the flow of gastric juice and of saliva are associated and synchronous. He inferred that the acidity of the gastric secretion was due to phosphoric acid, a misconception corrected shortly after (1825) by Prout.

PROUT, WILLIAM (1785-1850).

On the Nature of the Acid and Saline Matters Usually Existing in the Stomachs of Animals.

In: Phil. Tr., Lond., 1824, pp. 45-49.

The first English physiological chemist and distinguished in this field by his discovery that the stomach contains free hydrochloric acid.

#### EXPERIMENTAL PHYSIOLOGY

MAGENDIE, FRANCOIS (1783-1855).

Memoire sur le vomissement.

Paris, Crochard, 1813.

The pioneer experimental physiologist of France, he was an ardent defender of animal experimentation and the founder of modern experimental pharmacology and demonstrated the action of many drugs, which he introduced into medical practice. His contributions are numerous, though Garrison says of him: "He discovered only isolated facts, did not try to connect them with one another by any special hypothesis, and so arrived at no important generalizations." He was the teacher of an illustrious pupil, Claude Bernard.

He made important investigations into the mechanism of deglutition and vomiting.

BEAUMONT, WILLIAM (1785-1853).

Experiments and Observations on the Gastric Juice.

Plattsburgh, Allen, 1833.

The unique accident which made possible the far-famed observations on the digestive processes in man is herein described. A Canadian half-breed, Alexis St. Martin, sustained a gunshot wound of the abdomen. He survived, but with a gastric fistula. Beaumont availed himself of this unusual opportunity to make the most significant contribution to gastric physiology prior to Pavlov. He found that digestive juices were secreted only when there was food in the stomach and that simple irritation of the mucous membrane would not initiate a flow of gastric juice. He studied the digestibility of various foods, the influence of emotions, of work and of illnesses upon gastric secretion and digestion.

BERNARD, CLAUDE (1813-1878).

Du suc pancreatique et de son role dans les phenomenes de la digestion.

In: Arch. gen. de med. 4 ser. 19 :60-81, 1849.

Trained in his youth by the Jesuits, Claude Bernard was a pharmacist and a playwright before turning to the pursuit of medicine. He was a pupil of Magendie and his natural talents as a pioneer in experimental physiology made possible his numerous contributions in that field.

His greatest gift to gastro-intestinal physiology was his work on the pancreatic juice (1849-1856), in which he showed the effect of the pancreatic secretion in emulsifying fats and in converting starches into sugars, also its solvent action on proteins.

KUHNE, WILLY (1837-1900).

Ueber das Trypsin (Enzym des Pankreas).

In: Verhandl. d. naturhist.-med. Vereins zu Heidelberg, (1876), n. F. 1 :194-198, 1877.

Kühne was a pupil of Claude Bernard and was Professor of Physiology both in Amsterdam and in Heidelberg. His chief contributions to gastro-intestinal physiology are his chemical studies of the intermediate digestion of proteins and his discovery of the proteolytic enzyme in pancreatic juice, which he called "trypsin."

PAVLOV, IVAN PETROVICH (1849- ).

The Work of the Digestive Glands. 2. English ed.  
London, Griffen, 1910.

Pavlov, the son of a Russian priest, was a pupil of Heidenhain and of Ludwig. From the former he learned the technique of animal surgery and acquired an extraordinary ambidexterity. He was the founder of an eminent school of experimental physiologists.

Opened at pp. 16-17.

Illustration of his gastric pouch. By feeding a dog with such a pouch he was able to demonstrate "psychical secretion" of gastric juice. He showed that section of splanchnic nerves had no effect whereas section of the vagi would stop reflex gastric secretion.

He also studied pancreatic secretion and observed that pancreatic juice was activated by a duodenal substance which he named "enterokinase."

CANNON, WALTER BRADFORD (1871- ).

The Movement of the Stomach Studied by Means of the Roentgen Rays.

In: Am. J. Physiol. 1 :369-382, 1898.

Cannon conceived the idea of studying the movements of the gastro-intestinal tract in animals experimentally by means of the x-ray, utilizing bismuth subnitrate as an opaque medium.

Opened at pp. 370-371. Plate demonstrating the original tracings of the stomach of the cat at successive intervals following a bismuth meal.

#### HISTORY OF THE STOMACH TUBE

HUNTER, JOHN (1728-1793).

A case of Paralysis of the Muscles of Deglutition Cured by an Artificial Mode of Conveying Food and Medicine into the Stomach.

In: Tr. Soc. for Improvement of Med. & Chir. Knowledge, Lond., 1 :182-188, 1793.

Hunter came to London in 1748 and studied anatomy under his brother William, and surgery under Cheselden and Pott. He is considered the founder of experimental and surgical anatomy. He has been hitherto regarded as the first to introduce artificial feeding through a flexible tube passed into the stomach, but there is now good evidence that Alexander Monro (secundus) employed this method prior to Hunter's time.

MONRO, ALEXANDER (secundus) (1733-1817).

Operations in Surgery (manuscript notes of a student), 1775-1790.

Monro was a member of the famous family of surgeons and anatomists whose lives are so closely connected with the development of the Medical School of the University of Edinburgh. He succeeded his father as Professor of Anatomy and Surgery there and lectured between 1759 and 1800.

The manuscript here presented is in the hand of Samuel Davidson, who was a pupil of Monro between 1775 and 1790. These notes, taken at Monro's lectures, contain a description of a disease of the oesophagus with constriction and narrowing, as well as a symptom complex closely resembling cardiospasm.

For these conditions Monro recommended the passage of bougies, and suggested that by passing a hollow flexible tube, the purpose of the bougie and a means of feeding the patient would be provided by one instrument.

LARREY, DOMINIQUE JEAN (BARON) (1766-1842).

Memoires de chirurgie militaire et campagnes.  
Paris, J. Smith, 1812.

Baron Larrey, the greatest French military surgeon of his time and a favorite of Napoleon during his campaigns,

devised many operations and contributed much to military surgery.

He was the first to use intubation of the oesophagus in cases of gunshot wounds, devising the method as a means of feeding the famous Marshal, Baron Desault, who was suffering from paralysis of the oesophageal muscles as a result of a penetrating bullet wound.

JUKES, EDWARD (fl. 1822).

New Means of Extracting Opium, &c. from the Stomach.

In: London M. & Phys. J. 47 :384-389, 1822.

Jukes and Francis Bush wrote simultaneously on the subject of lavaging the stomach by means of a hollow flexible gum tube in cases of opium poisoning. Neither writer knew of the work of the other, nor did they know that Physick, an American (1800) had utilized intubation in a very similar manner.

A letter by Bush: "On removing opium from the stomach with a syringe" will be found on p. 541 of this journal.

EWALD, CARL ANTON (1845-1915).

Beitrage zur Physiologie und Pathologie der Verdauung.

In: Virchow's Arch. 101 :325-375, 1885.

Ewald was an assistant to Frerichs and was Senator's successor at the Kaiserin Augusta Hospital. He is known for his valuable contributions to the knowledge of disorders of digestion. He published his work on intubation for examination of the stomach in 1875, and in conjunction with Boas, his description of the "test breakfast" in 1885. This simple meal of bread and tea became the standard test meal and is still in universal use.

EINHORN, MAX (1862- ).

Die neueren Methoden der Magenuntersuchungen.

Reprinted from: New Yorker med. Monatschr. 1 :113-122, 1889.

Einhorn was a graduate of the University of Berlin and later became a practitioner and teacher in New York. He was the inventor of many ingenious diagnostic devices, among them the stomach bucket, in 1890, and the duodenal bucket, in 1908.

#### CLASSICAL DESCRIPTIONS OF GASTRIC ULCER

DONATUS, MARCELLUS (LATTER HALF OF 16TH CENTURY).

De Historia Medica Mirabili Libri Sex.

Francofurti ad Moenum, impensis J. J. Porsii, 1613.

Donatus studied medicine at Padua. He practiced in Venice and later went to Mantua, where he became Secretary of State and was made a Count.

He published in Mantua in 1586 his *De Historia Medica*, in which is found the earliest known report of a gastric ulcer discovered at autopsy. The edition here shown is the one published in Frankfurt after his death. Opened at pp. 308-309.

BAILLIE, MATTHEW (1761-1823).

The Morbid Anatomy of Some of the Most Important Parts of the Human Body. 2. ed.

Lond., J. Johnson, 1797.

Baillie was urged to study medicine by his uncle, the celebrated William Hunter, and became a pupil of Hunter and of Morgagni. He was an eminent practitioner in London, as well as an astute student of pathology. His works show a systematic attempt to correlate pathology and clinical medicine.

In the book exhibited, which was first published in 1793, he gives the first clear description of the morbid anatomy and the clinical symptoms of gastric ulcer.

Opened at pp. 140-141.

**ABERCROMBIE, JOHN (1780-1844).**

Pathological and Practical Researches on Diseases of the Stomach, the Intestinal Canal, the Liver, and other Viscera of the Abdomen.

Edinb., Waugh & Innes, 1828.

Abercrombie received his doctor's degree at Edinburgh in 1803 and after spending a year in further study at St. George's Hospital, London, returned to Edinburgh to practice. He kept with scrupulous care a record of every case of scientific interest that came before him and many of these observations are incorporated in his two principal works.

Opened at pp. 34-35 showing a description of a case of gastric ulcer, in which the symptoms of perforation and hemorrhage are noted and excellent recommendations concerning treatment are made.

**CRUVEILHIER, JEAN (1791-1874).**

Maladies de l'estomac. In his: Anatomie pathologique du corps humain.

Paris, Bailliere, 1835-42, Vol. 2.

Cruveilhier graduated in 1816 from the University of Paris, where he was a pupil of Dupuytren. He returned to Limoges to practice, but was persuaded to return to Paris as Professor of Pathology.

His *Anatomie pathologique du corps humain* is a remarkably illustrated atlas of gross pathology. Plates showing ulcers of the stomach are here shown. It is often claimed that his was the first pathologic description and depiction of gastric ulcer, and the name "Cruveilhier's ulcer" was much in use in France. However, he was preceded by Abercrombie and Matthew Baillie. Cruveilhier is rightly credited with the differentiation of benign gastric ulcer and carcinoma, but microscopic studies are lacking.

**DIEULAFOY, GEORGES (1839-1911).**

Exulceratio simplex, diagnostic anatomique et diagnostic clinique.

In his: Clinique medicale de l'Hotel-Dieu de Paris, 2 :23-62, 1897-98.

Dieulafoy was a distinguished practitioner of Paris but although an alert and intelligent physician and an excellent teacher he was not a profound scientific investigator. His work on internal medicine was very readable and popular.

He differentiated acute gastric ulcer which he called "exulceratio simplex" from chronic gastric ulcer, "ulcus simplex" of Cruveilhier. He advanced a toxi-infectious theory of the etiology of acute ulcers and thought that they were the precursors of chronic ulcers. Among his case reports are instances of fatal gastric hemorrhage from acute gastric ulceration at the fundus.

**DUODENAL ULCER; TYPHOID AND TYPHUS FEVERS  
PATHOLOGICAL ANATOMY**

**HAMBERGER, GEORGIUS ERHARDUS (1697-1755).**

De Ruptura Intestini Duodeni.

Jenae, lit. Ritterianis, [1746].

Hamberger received his doctor's degree at Jena in 1721 and was later Professor of Chemistry, and practiced at that University.

He described, in 1746, the case of a young woman who, after gathering plums in the morning, was seized with violent abdominal pains and died in a short time. Upon opening the abdomen post-mortem Hamberger found gas, fluid, and in the duodenum a perforation the size of a pea. This is probably the first reported case of a *perforated duodenal ulcer*.

**MOYNIHAN, BERKELEY GEORGE ANDREW MOYNIHAN, 1ST BARON (1865- ).**

On Duodenal Ulcer and its Surgical Treatment.

In: Lancet, 2 :1656-1663, 1901.

a military surgeon. His contributions to abdominal surgery are numerous and important.

His great pioneer work in surgery was his account of the characteristics and symptoms and surgical treatment of duodenal ulcer. Isolated pathological reports of this condition had occasionally been noted and been lost in obscure literature but its occurrence, remarkable frequency, and clinical characteristics were first adequately described by this author.

**BRETONNEAU, PIERRE (1778-1862).**

Notice sur la contagion de la dothinerenterie; lue a l'Academie Royale de Medecine, le 7 juillet 1829.

In: Arch. gen. de med. 21 :57-78, 1829.

Bretonneau wrote on typhoid fever in 1829, describing at that time the lesions in Peyer's patches. He also anticipated the differentiation of typhoid and typhus fevers and was an early supporter of the germ theory of disease.

**LOUIS, PIERRE CHARLES ALEXANDRE (1787-1872).**

Recherches anatomiques, pathologiques et therapeutiques sur la maladie connue sous les noms de gastro-enterite, fièvre putride, adynamique, ataxique, typhoide. . . Paris, Bailliere, 1829.

This is the first time that the name *typhoid* fever rather than *dothinerenteritis* was applied to this disease.

Louis was famous as a teacher of American physicians. Through his influence on such men as O. W. Holmes, the Shattucks, Gerhard and others, he extended a dominating influence upon medicine in the United States.

**MORGAGNI, GIOVANNI BATTISTA (1682-1771).**

De Sedibus et Causis Morborum. . .

Venetis, ex typ. Remondiniana, 1761. 2 vols. in one.

Morgagni received his medical education at Bologna and was much influenced by his teacher, Valsalva. At the age of 29 he was called to Padua as Professor of Surgery to fill the chair once occupied by Vesalius. His life was spent apart from the affairs of the world in indefatigable labors in dissection, clinical consultations and teaching, with no thought of self interest or renown.

The works of Morgagni were not published until his seventy-ninth year, when they appeared in the form of five books of informal letters. This work constitutes the foundation of modern pathologic anatomy, bringing about for the first time a systematic correlation of clinical data and post-mortem findings. He was the first to describe the clinical and pathologic features of acute yellow atrophy of the liver. In 1733 Morgagni described a case of duodenal ulcer complicating ulcers of the stomach.

This book is opened at vol. 2, p. 73, to a section in which this very astute clinician and pathologist describes and discusses a case of "emotional jaundice."

**BRIGHT, RICHARD (1789-1858).**

Cases and Observations Connected with Disease of the Pancreas and Duodenum.

In: Med.-Chir. Tr., Lond., 18 :1-56, 1833.

Bright was a pupil of Sir Astley Paston Cooper. He was physician to Guy's Hospital for 23 years and the ward where he made his rounds still bears his name. The leading consultant of London in his time, he was known for his dissection of autopsy material as well as for the practice of clinical medicine.

He described essential nephritis and first differentiated between cardiac and renal dropsy. In the field of gastroenterology his clinical descriptions and pathologic studies in pancreatitis and diabetes are classic gems of medical literature.

Account of a Remarkable Misplacement of the Stomach.

In: Guy's Hosp. Rep., 1:598-603, 1836.

The first pathological and clinical description of a congenital thoracic stomach. Clinical knowledge of this remarkable condition is just appearing in very

MEGACOLON; CONGENITAL PYLORIC STENOSIS;  
APPENDICITIS

RUYSCH, FREDERICUS (1638-1731).

Observationum Anatomico-chirurgicarum Centuria.

In his: Opera Omnia, Amstelodami, apud Janssonio-Waesbergio, 1737, vol. 1, 86.

A pupil of Sylvius, Ruysch, like the physicians of his time, had wide interests such as botany, chemistry, numismatics. He was primarily an anatomist and pathologist; his name is associated with the practice of injecting arteries with colored wax and he is remembered for the excellence of his anatomical illustrations.

Observatio XCII. *Enormis intestini coli dilatatio*. Ruysch was probably the first to report (1691) the findings of an enormous dilatation of the colon in a girl fifteen years of age. The specimen is apparently one of "idiopathic congenital dilatation of the colon" described clinically, *de novo*, almost 200 years later by Hirschsprung.

HIRSCHSPRUNG, HARALD (1831-1916).

Stuhltragheit Neugeborener in Folge von Dilatation und Hypertrophie des Colons.

In: Jahrb. f. Kinderh. 27 :1-7, 1888.

Hirschsprung was Chief of Staff of the Children's Hospital of Copenhagen from 1870. Besides his original description of *dilatation and hypertrophy of the colon in the newborn*, he published papers on congenital occlusion of the oesophagus and of the duodenum, acute rachitis, rheumatic myositis in children, etc.

LEWITT, WILLIAM (fl. 1867).

Enlargement of the Colon.

In: Chicago M. J., 24 :359-361, 1867.

William Lewitt, otherwise unknown in American medicine, was the first American to describe, in 1867, a case of congenital dilatation of the colon, with clinical features and post-mortem studies. This publication antedates that of Hirschsprung by almost 20 years. Lewitt was at that time a demonstrator in Anatomy at Rush Medical College, but no further biographical data are available.

WILKS, SIR SAMUEL (1824-1911).

Lectures on Pathological Anatomy.

London, Longman, 1859.

These studies are the result of a life devoted to clinical medicine and clinical pathology at Guy's Hospital. Among the many brilliant and original descriptions in this volume is one of a type of ulceration of the colon which had hitherto not been differentiated from dysentery or similarly identified forms of colitis. Wilks is here undoubtedly describing a specimen of *severe ulcerative colitis* of the type today classed as "non-specific."

Opened at p. 301.

FERNELIUS AMBIANUS, JOANNES (1497-1558).

Universa medicina.

Francfurti ad Moenum, apud A. Wechelum, 1577.

Fernel, besides being famed as a medical practitioner, was active in many fields of research, being the first to measure accurately a degree at the meridian.

Opened at Book VI, p. 218.

The accompanying selection from his *Universa Medicina* is probably the first description of acute appendicitis with perforation. The only doubt hinges on whether the terms *caecum intestinum* refers to the caecum or the appendix, as anatomists of that time used the term to apply to both structures.

PARKINSON, JAMES (1755-1824).

Case of Diseased Appendix Vermiformis.

In: Med.-Chir. Tr., Lond., 3 :57-58, 1816.

Parkinson was the son of a physician and one of a cultured and educated family. Little is known of his education, but he was engaged in practice in 1785 and attended John Hunter's lectures in surgery during that year. He will be remembered in the main for his classical description of paralysis agitans. He was also a reformer and

political agitator. One of the early classical descriptions of appendicitis, the first one in English, is written by this author. He recognized perforation as the cause of death in this condition.

FITZ, REGINALD HEBER (1843-1913).

Perforating Inflammation of the Vermiform Appendix, with Special Reference to its Early Diagnosis and Treatment.

In: Boston M. &amp; S. J., 115 :13, 1886.

Fitz received his degree at Harvard in 1868. He spent two years abroad with Rokitansky, Oppolzer and Skoda in Vienna, and with Cornil in Paris. He found his greatest inspiration in Virchow, whose theory of cellular pathology he introduced into the United States. In 1870 he returned to Boston and led an active life in practice and teaching. This classical article on appendicitis was presented before the Association of American Physicians in 1886. Here was expounded for the first time a clear picture of the clinical course and diagnostic signs of appendicitis, together with its pathologic changes. Fitz advocated immediate operation as the only rational means of saving life.

## ABDOMINAL SURGERY

BOBBS, JOHN STOUGH (1809-1870).

A Case of Lithotomy of the Gall Bladder.

In: Indiana M. J., 18 :177-180, 1899.

Bobbs, a pioneer surgeon of Indiana, read medicine with Martin Luther of Harrisburgh, Pa. and took a course of lectures at Jefferson Medical College in Philadelphia. He soon took high rank both as a physician and surgeon. When the Medical College of Indiana was organized, he was elected Professor of Surgery and later Dean of the Faculty. The latter part of his life was devoted mainly to surgery, and as an operator he was bold and original.

He performed the first cholecystotomy in 1867. The account of it was published originally in the *Transactions of the Indiana State Medical Society* in 1868 and the above reference is a reprint, somewhat abridged.

VON VOLKMANN, RICHARD (1830-1889).

Ueber den Mastdarmkrebs und die Extirpatio recti.

In: Samml. klin. Vortr. 131 (Chir. 42), 1878.

von Volkmann was the son of a well known physiologist and professor of surgery at Halle. He graduated in medicine from Berlin in 1854 and became an assistant in the surgical clinic of Blasius. He later returned to Halle to practice and to teach surgery.

He is remembered largely because of his description of ischemic contraction, but it must be noted that he was the first to perform a resection of the rectum for carcinoma in 1878.

## DEVELOPMENT OF RADIOGRAPHY

CANNON, WALTER BRADFORD (1871- ).

The Movement of the Stomach Studied by Means of the Roentgen Rays.

In: Am. J. Physiol., 1 :369-382, 1898.

This constitutes the pioneer attempt to apply the recently discovered radiographic technique to gastro-intestinal physiology. The use of bismuth subnitrate was not only a successful technical innovation, but it made possible physiological studies on peristalsis and intestinal function never before envisioned in a normal animal. (See also item no. 32.)

ROUX, JEAN CHARLES &amp; BALTHAZARD, VICTOR (1872- ).

Etude du fonctionnement moteur de l'estomac a l'aide des rayons de rontgen.

In: Arch. de physiol., 5. ser., 10 :85-94, 1898.

This article is the earliest to incorporate the idea of Cannon and to apply the bismuth contrast meal to human beings. Unfortunately the amount of bismuth subnitrate used was insufficient. This suggestion was but little improvement on the filled capsules, metal foreign bodies, coiled metal springs, and bags filled with solution of lead

acetate which were among the fantastic devices for visualizing the stomach during this initial period.

WILLIAMS, FRANCIS HENRY (1852- ).

The Roentgen Rays in Medicine and Surgery.  
N. Y., Macmillan, 1901.

Williams was educated at the Massachusetts Institute of Technology and at Harvard Medical School. He studied in Europe for two years and returned to enter general practice in 1879. He then took up the study of roentgenology to which he devoted himself thereafter. He taught X-ray diagnosis and therapy at Harvard and wrote much on the subject.

The textbook here shown, opened at p. 361, is one of the earliest in which the opaque meal was expounded as a practical mode of gastro-intestinal diagnosis. Here for the first time bismuth was used in sufficient concentration for the outline and study of the normal human stomach. This American pioneer work antedated by three years that of Rieder of Germany.

REIDER, HERMANN (1858-1932).

Radiologische Untersuchungen des Magens und Darmes beim lebenden Menschen.

In: Munchen. med. Wchnschr., 51 :1548-1551, 1904.

Studied in Vienna, Heidelberg and Munich, at which latter place he received his doctor's degree. Served on the staff of the Munich Hospital, the Medico-Clinical Institute, and under the renowned Ziemssen. He was attracted by Rontgen's discovery (1895) to such an extent that in 1901 he was already beginning to study the form and function of the alimentary tract of man by means of radio-opaque meals of bismuth. This article is the first accurate description of the radiology of the normal alimentary tract of man. It is a classic study, exact, detailed, perfect in observation.

HOLZKNECHT, GUIDO (1872-1931) & JONAS, SIEGFRIED (1874- ).

Die radiologische Diagnostik der intra- und extra-ven-trikularen Tumoren und ihre spezielle Verwertung zur Fruhdiagnose des Magencarcinomas.

Wien, Perles, 1908.

Holzknacht studied in Strassburg and Konigsberg and received his doctor's degree in Vienna in 1901. He then became an assistant in Nothnagel's clinic where he became interested in roentgenology. He studied this subject ardently for many years and was famed as a teacher and as a pioneer in the development of the clinical use of the X-ray. He was the first to devise a dosage table for X-ray therapy and did much to clarify the problems of the diagnosis of visceral disease.

His work on tumors of the stomach deals particularly with the roentgen diagnosis of carcinoma of the stomach.

COLE, LEWIS GREGORY (1874- ).

The Diagnosis of Post-pyloric (Duodenal) Ulcer by Means of Serial Radiography.

In: Tr. XVII. Internat. Cong. Med. (1913), Lond., Sect. XXII., part II (Radiology), pp. 77-81, 1914.

Cole graduated from the College of Physicians and Surgeons in 1898 and was Professor of Roentgenology at Cornell Medical College from 1913 to 1920.

A very few years after Moynihan's description of duodenal ulcer (1905), Cole's work describing the "Pileus duodeni" appeared. This pioneer work on the roentgenography of the duodenal cap remains a classic contribution.

"TWO-AND-A-HALF-FOOT SHELF" OF A GASTROENTEROLOGIST

This represented a choice of some (not all) of the modern classics considered essential to a proper understanding of gastroenterology and its relation to internal medicine. The books were chosen by one of us.

# ABSTRACTS

JOHN R. PARRY AND KENNETH MURRAY.

*Acute Pancreatic Necrosis—a review of 20 cases.*  
*Can. Med. Assoc. Journal, Dec., 1934, p. 592-5.*

The writers think pancreatitis is probably more common than is generally supposed. The review is based on 20 cases, in which the diagnosis was confirmed by operation or necropsy. In the series there was no classical case with agonising pain, cyanosis and collapse. In most of cases, the pre-operative diagnosis was cholecystitis; and operation not urgently required. There were twice as many females as males.

Infection or exciting agents can reach the pancreas in one of 5 ways: by blood or lymph, direct extension, regurgitation from duodenum or from the bile ducts. Blood infections occur in mumps. Infection through the lymph channels from an inflamed gall bladder they think is doubtful as in none of their cases was the gall bladder very acutely diseased. Just as we get infection of the parotid from the mouth, we may get the pancreas infected from the duodenum. A case is cited of a child who 36 hours earlier had received a blow on the abdomen. At operation there were the signs of pancreatitis. The explanation offered is that a sudden increase of intra abdominal pressure caused a squirt of duodenal contents or bile into the pancreas, causing necrosis.

The pancreatic duct may terminate in one of three dif-

ferent ways. In one way, where it joins the common duct above the ampulla, it is possible for a stone to block the flow of bile into the bowel and cause it to be forced along the pancreatic duct. Again the pancreatic duct may empty in the bowel through an opening distinct from the common bile duct. In this type it would be impossible to get regurgitation from blockage of the common duct, yet in 2 of the fatal cases this was the form of termination of the pancreatic duct.

The cases showed white blood counts of 15 to 20 thousands, in the traumatic cases it was higher. Clinically pancreatitis resembles acute cholecystitis, but is more severe, and the authors believe that such a case not relieved by one or two hypodermics of morphia is likely pancreatitis. Pain and tenderness, to the left of midline and vague thickening in the epigastrium aid in making a diagnosis.

As to treatment trans-abdominal drainage is useless. Cholecystotomy is quickly carried out and will drain a likely source of infection and relieve tension. Saline and glucose intravenously are given for dehydration from vomiting and morphia for pain.

Immediate operation in the acute cases is not recommended. Removal of infected gall bladders is recommended as a prophylactic measure.

R. H. M. Hardisty, Montreal.

## SECTION XII—"The Clinic"

### Gastric Ulcer Following Duodenal Ulcer With Obstruction: Report of a Case<sup>\*</sup>

By

FRED R. HARPER, M.D.  
TUCSON, ARIZONA

THE sequence of events in this case makes it of interest even though the lesion itself is not rare.

Robertson and Hargis (1) found ulcers in both the stomach and the duodenum in twenty-seven (7 per cent) of 387 cases. In all of the 387 cases ulcers were found in either the stomach or duodenum. The cases were taken from 2000 autopsy records. Walters (2) studied the rou-

tine pathological specimens of resected stomachs from German Clinics and compared them with routine cases in this country. He concluded that gastritis and gastric ulceration associated with duodenal ulcer was much more common in Germany. He quotes Konjetzny as finding gastric changes constantly associated with duodenal ulceration. However, in a selected group of cases in which Walters did gastric resections at the Mayo Clinic, he found only two cases

in which there was gastritis or gastric ulceration. The following case is of interest because the duodenal ulcer with gastric retention was demonstrated nine months before the associated lesion was found in the stomach.

#### CASE REPORT

The patient was a male, aged 33 years. He was first seen in August, 1933. At that time he had been vomiting coffee ground material for one week. He had also had tarry stools. He

<sup>\*</sup>From the Thomas-Davis Clinic.  
Submitted April 10, 1935.

gave a history of having had epigastric pain for two years. The pain came on three or four hours after meals and was relieved by soda or vomiting, which he frequently induced for relief. Examination revealed no abnormality ex-

Fig. 1. Radiogram of stomach taken at the time of the patient's first visit. The deformity of the duodenal cap may be noted. There is no definite evidence of gastric ulceration.

## Abnormal Motility

Gastro-Intestinal symptoms may be successfully controlled by the application of

### Bile Salts Therapy

## TAUROCOL

(TOROCOL)

### Bile Salts Tablets

Increase motility, increase peristalsis, step up the flow of bile by stimulating the bile producing cells of the liver. The gradual reduced dosage of Taurocol permits of the restoration of the normal motility.

cept for slight tenderness in the epigastrium.

Laboratory reports showed the hemoglobin to be 37%, red blood cells 2,200,000, white blood cells 8,500.

X-ray of the stomach showed marked spasm of the pylorus with a constant deformity of the duodenal bulb. The stomach did not empty in the usual 6 hours. The X-ray diagnosis was duodenal ulcer with gastric retention.

Surgery was advised but after a brief period of hospitalization the patient left against advice and was not seen again until June, 1934. For four months previous to his second visit, he had been vomiting every four or five days. For the two days previous to his return, he had vomited everything he had taken by mouth. The vomitus contained blood; he had had tarry stools.

He was found to have 1500 cc. of gastric retention. No X-ray study was

Elman and Eckert (5) have mentioned the importance of pyloric obstruction in producing increased gastric acidity. Bolton (6), in 1909, found that ulcers in cats showed delayed healing in the presence of pyloric stenosis. Friedman (7) and Hamburger produced acute ulcers with silver nitrate and caused them to become chronic by partially occluding the pylorus. Robertson and Hargis emphasized the importance of stenosis in the non-healing of peptic ulcers. Horsley (8) mentions

## LAROSTIDIN

*"produces rapid clinical improvement . . .  
gastroduodenal ulcer . . . . .  
liberal diets . . . . . ambulatory."\**

Fig. 2. Gross specimen of resected stomach showing large ulcer on the lesser curvature. The duodenal ulcer was partially crushed by the clamp.

made because of the retention. After three days of preparation with intravenous glucose, exploratory laparotomy was done. A large ulcer 3½ cm. in diameter surrounded by considerable gastritis was found on the lesser curvature of the stomach. There was also a definite ulcer in the duodenum.

A posterior Polya type of gastric resection was done removing about two-thirds of the stomach. The patient's convalescence has been uneventful and he is now able to eat without distress.

### COMMENT

In a recent experimental study, I (3) suggested the importance of chemical and mechanical factors in the development of peptic ulcers. Numerous other experimental studies have emphasized these factors. Steinberg and Starr (4) and also

The evidence pointing to the efficacy of Larostidin in ulcer management continues to accumulate.

In examining that evidence one finds a striking unanimity of opinion. Clinicians who have recorded their observations consider the Larostidin treatment the foremost advance in ulcer therapy. The relief, they find, is prompt. Pain, vomiting, hypersecretion, and retention quickly disappear. Appetite returns; there is a gain in weight; the entire picture changes.

According to Volini and McLaughlin\* these good results may be attributed to the decreased secretion of gastric acid—the direct result of Larostidin injections.

### HOW TO USE LAROSTIDIN 'ROCHE'

*Usual Dose:* One ampul Larostidin (5 cc.) by intramuscular injection once daily for about 24 days. . . . It is good practice to give the injections at about the same time daily and not

to skip any. Usually, about 24 injections are sufficient. Inject alternately in the arms or in gluteal muscles, preferably the latter. Inject slowly, gradually withdrawing the needle.

*Larostidin ampuls, 5 cc., cartons of 6*

that there are some who believe that duodenal ulcer may be caused from adhesions or from pressure of the mesenteric artery on the terminal duodenum. Puhl (9) commenting on gastrojejunal ulceration says that stenosis of the stomach can lead to a diffuse and even ulcerative fundus gastritis. In view of these observations, it would seem that the duodenal ulcer and resulting stenosis may have been a factor in the etiology of the gastric lesion found in this case nine months later.

Various methods of treatment such as excision with pyloroplasty or gastroenterostomy have been used in dealing with associated gastric and duodenal ulcers. However, in this

case, because of the extent of the lesions and the possibility of malignancy, gastric resection was done.

### SUMMARY

A case is reported in which gastric ulcer developed during a nine months period after the finding of a duodenal ulcer with retention. The possibility of the duodenal ulcer, with its resulting retention of gastric secretion, as a factor in the development of the gastric ulcer is discussed. The condition was relieved by extensive gastric resection.

## Recent Development in the Study of Oral Bacterial Flora\*

By

LLOYD ARNOLD, M.D.

and

CARROLL W. STUART, D.D.S., M.D.

CHICAGO, ILLINOIS

THE oral cavity has been considered by many to be normal in healthy individuals and to possess a rather constant bacterial flora. Those parts of the oral cavity of greatest interest to the dentist oftentimes are the first to undergo demonstrable secondary changes due to systemic or metabolic diseases. The oral cavity must possess some defensive mechanism against seeding itself with various and sundry types of bacteria. Several workers in this laboratory have studied the normal bacterial flora of the skin, nose, eye, gastro-intestinal tract and other body surfaces. We have included in our studies certain observations upon the mechanism of control of the endogenous and exogenous bacterial life on a healthy epithelial surface. This paper will record some of our work upon the bacterial flora of the oral cavity.

The first question to be discussed is the difficulty of finding a really healthy mouth. Allen (1913) said: "The artificial conditions of modern life have rendered it peculiarly difficult to secure for investigation an adequate number of individuals any part of whose respiratory tracts could be regarded as strictly healthy, especially from a bacteriological standpoint." There are persons whom we recognize as "carriers of pathogenic bacteria." For example, most people harbor the *Micrococcus catarrhalis* in their nasal passages and yet rarely suffer from the acute reaction, others carry pathogenic strains of pneumococcus or perhaps strains of *Bacillus diphtheria* may be cultured from human throats without the person ever suffering with these diseases. They may even be entirely ignorant of harboring such organisms. We might try to conclude that these bacteria are not pathogenic if we were not sure the contrary to be the case. A very thorough examination of every mouth and throat will disclose various sized areas of gingivitis, a carious tooth, paradental gingival pockets perhaps around the third molar, follicular tonsillitis, inflamed dental papillae, an infection in the supratonsillar fossa which is always difficult to detect, a granular pharyngitis, or some other condition of which the patient may not be aware. Any one of these infected areas will so change the oral flora

that we have no right to classify the mouth as a normal. A review of the literature leads one to conclude that with one or more of these conditions classed as a normal then the numbers, types, and strains of bacteria to be found are so varied as to render the problem of investigating a normal mouth a hopeless task. Allen (1913) therefore, stated: "Any attempt at discussion as to what is the bacteriology of the healthy mouth would be of purely academic interest, inasmuch as the perfectly healthy mouth is for all intents and purposes non-existent."

Our investigations not only bore out the findings of Allen and others but led us to conclude that even the different areas of the mouth vary in bacteriological content. Changes in the bacterial flora were noted on the same areas in a relatively short time. This was especially characteristic on the dorsum of the tongue.

It is reasonable to expect to find a great variety of micro-organisms in the oral cavity because the air we breathe, the water we drink, and the food we eat contain innumerable species of bacteria. The lips come in contact with many different articles during a day, thus frequently seeding bacteria onto the mucosa of the lips. The tongue licks the bacteria back into the oral cavity from this seeding zone in great numbers. Food may be deposited in crevices of the tongue and the gums, in cavities of the teeth, and the interdental spaces between the teeth where the bacteria in such particles may grow under ideal environmental conditions. Miller (1892) described over 100 different varieties of micro-organisms in the mouth and the more carefully we go into this problem with modern methods the greater are the varieties which come to light until we are entirely bewildered and confused in an almost mass of bacterial species.

J. and R. Cruickshank (1931) stated that the bacterial flora of the mouth is extremely complicated and in addition may undergo variations from time to time and these factors place a great variety of difficulties in the way of investigating pathological lesions of the gums and teeth. The authors state that the view so widely held by clinicians, that many general bacterial infections and toxemias in the human subject have their portal of entry in carious or dead teeth and are disseminated by the associated lymphatics, rests upon

slender bacteriological foundations. The factors just mentioned render research on this aspect of medicine a subject of great complexity. These writers found that the bacterial flora of the mouth changes from week to week and even from day to day. They conclude that the types of research carried out recently by groups of observers who take swabs from the throats of many individuals at monthly intervals and tabulate the percentage of persons harboring certain organisms is of little value.

The adventitious or exogenous bacterial flora of the mouth is that which is constantly gaining entrance with air, dust, food, and water. It is this flora that is constantly being eliminated and seems to be very transient. Miller (1890) was one of the first to point out how rapidly the adventitious flora was removed from the mouth. He rinsed his mouth with highly concentrated suspensions of lactic acid bacilli and was able to show practically none of these organisms present by the next morning. Bloomfield (1919, 1920, 1921) called attention to the rapid disappearance of foreign organisms by the flushing mechanism of the mouth secretions. He expressed the opinion that except for local infections or transient invasion under special conditions, transient organisms do not as a rule grow freely on the mucous membrane of the oral cavity. In his review of the literature concerning the protective mechanism of the mouth he lists the possible factors of importance as: (a) anatomical conditions, (b) the flushing mechanism, (c) bactericidal action of secretions, (d) reactions of the secretions, (e) the antagonistic action toward invaders of the endogenous flora.

Bloomfield (1922) referred to the circulation of bacteria in the mouth. He described how bacteria, by means of suction currents, were carried from the lips backward toward the throat. These transient organisms are not easily attached to the mucous membrane of the mouth but once they do become fixed to the tissues it is very difficult to dislodge them. This investigator attempted to remove the bacteria from the dorsum of the tongue by frequent washing, scrubbing, and irrigations which were carried out at 20 minute intervals. He was able to dispose of the transient bacteria but none of the attached flora. It is evident, therefore, that the bacteria of the normal flora do not grow freely in the mouth secretions but may do so in the crevices of the mucous membranes and in the openings of the ducts of the glands. The organisms which had become attached to the mucosa could not be dislodged by the application of an hypertonic salt pack. He concludes that any of the organisms which remain in the mouth for a few hours must be in "vital biological relationship" to the mucous membrane, or they would be removed by mechanical means. Furthermore, the saliva plays no significant role in the propagation of bacteria but can assist as a vehicle in the process of expectoration and swallowing which after all are the two most important methods of bacterial elimination from the oral cavity and throat.

The intrinsic or endogenous flora consists of those organisms which are attached to the tissues and, according to Edington (1922) are introduced with food, water, and air, but Thomson and Thomson (1932) were unable to obtain cultures of bacteria which make up this flora from food, water, and air. They con-

clude that these bacteria are derived from previous human beings and perhaps animals.

Attention has been called to the fact that the oral flora varies in the different anatomical parts of the mouth and throat. Brailovisky—Lounkevitch (1915) found, upon examination of the cheeks, tongue and palate, organisms which were comparable with the flora of a suckling child, together with a different bacterial flora from the tongue and gums. Small and large gram-positive diplococci predominate in the films taken from these areas and with them were found a few leptothrix and spirilla. The same diplococci are found in great numbers on the tongue in addition to masses of staphylococci, short and long thin rods, spirochetes, leptothrix, filaments, and vibrios. The gums harbored a few cocci and other organisms occurred in numbers in different individuals; in some mouths great numbers of slender gram negative rods predominate, in others filaments of leptothrix and still in others spirochetes. Bacteria occurred in greater abundance among the villi on the back of the tongue than on the tip. The numbers vary greatly between the teeth, but the types consisted almost constantly of leptothrix threads, spirochetes and fusiform bacilli. The habitual flora of the mouth of adults was about the same as that of the child after dentition but greater variations occur according to the state of the mouth and the teeth. The fundamental flora consisted of streptococcus salivarius, together with various anaerobes, leptothrix, spirilla, vibrios, staphylococci and others.

The condition, as well as the arrangement of the teeth (presence of caries apparently affects the picture) and careful hygiene all materially influence the numbers of bacteria making up the flora. Complete removal of all of the teeth is associated with a return of the types of organisms to those found in the mouths of suckling infants. Space will not permit of a complete description of all anatomical areas.

There does not seem to have been much work done on the effect of the diet on the bacterial flora of the mouth. Howitt, Fleming, and Simonton (1928) placed a patient on each of several diets for a week at a time: (1) the usual diet, (2) two types supposed to have a detergent effect, (3) balanced diet, and (4) a so-called "sticky" type of food. Each diet was given at least twice, once with the use of the tooth brush and once without. In addition the patient was given liquid food through a stomach tube, and no tooth brush was used. Weekly quantitative and qualitative examinations were made of the mouth flora. Mouth organisms flourished readily on desquamated epithelium in the absence of food particles. The debris gathered after a sticky diet showed no more abundant growth than that after supposedly detergent diets except for a slight increase of aciduric rods on carbohydrate diet. Artificial cleansing with the tooth brush was more effective than a detergent diet, and when the tooth brush was not used the teeth were cleaner following the "sticky", balanced and ordinary diets than on detergent diet. When the tooth brush was used the appearance was similar in each case. One of their workers was used as a subject for a study of throat cultures over a period of a year. During this time he developed a duodenal ulcer and was fed through a tube passed into the duodenum. All food and water was administered via this tube. Throat cultures taken, during the time when no food or water touched the throat mucosa,

were similar to the findings obtained when he was on a normal diet.

Kuster (1913) states that nothing was known as to whether or not the normal bacteria in the mouth play any useful role in digestion or in keeping the mouth clean. During health the bacteria are evidently harmless but during times of lowered resistance and when the patient is suffering with local and systemic diseases these same organisms may penetrate into the deeper tissues and cause considerable damage. Kuster believed this occurs in cases of pyorrhea, diseases of the teeth and jaws, in necrotic anginas and in cancrum oris. When the organisms were swallowed and came in contact with the acid of the stomach they were dissociated or changed to a non-pathogenic state and never, under normal conditions, reach the duodenum unchanged. This was the reason why these organisms are considered to be absent in the duodenal flora. The bacteria found in the intestines are entirely different than those found in the oral cavity.

Thomson and Thomson (1932) state: "It seems to us that the bacteria of the mouth are of no value in human economy, except that perhaps their presence on the mucous membrane may prevent the settling down of other more dangerous bacteria. They may also stimulate the production of antibodies." . . . "It is our opinion our health would be greatly benefitted if the mouth could be kept sterile." Obviously good hygienic conditions of the oral cavity is of great value to health. Thomsons' definition of oral hygiene consists of the scrupulous cleansing of the teeth and gums, and the removal of all dead organic matter and debris. They recommend cleansing the mouth by the frequent use of the tooth brush and by the use of the weakest of antiseptic solutions. They contend that cleansing the oral cavity by washing was brought about more by the mechanical removal of bacteria and debris than by antiseptic action. The local production of acid has been thought to prevent putrefaction and fermentation but on the other hand weak acid solutions in contact with the teeth has been related to dental caries. The results of these findings and their value to health remain to be established.

The physiology and biochemistry of the oral secretions should be considered as their possible influence upon the bacterial flora of the mouth. The mucous membranes of the cheeks, palate, gums and tongue are covered with squamous epithelium and there are no cilia such as are present in the nose and nasopharynx. On the tongue there are microscopic papillae like those of the skin. Besides these the upper surface of the tongue is covered with larger papillae of three kinds: (1) the circumvallate papillae at the back of the tongue, (2) the conical papillae which are scattered over the entire surface, and (3) the fungiform papillae which are found among the conical papillae.

Mucus is secreted through most of these papillae but the glands of Ebner which open between the circumvallate papillae and a few others elsewhere in the mucosa secrete a serous material. In addition to these mucous and serous secretions the saliva flows in large amounts from the parotid and sublingual glands. Great numbers of epithelial cells are shed from the mucous membrane. The mucin and dead epithelial cells serve as an excellent culture media for bacteria which are

found on the surface in large numbers. Goodby (1931) concludes that the shedding of the epithelial cells is another way of cleansing the mouth. A film made from the buccal mucous membrane and stained with Leishman's stain shows a number of epithelial cells which have become detached and which are surrounded by large numbers of bacteria. Goodby believes the most important method of cleansing the oral cavity is the stirring up of the oral secretions by the mechanical movements of the cheeks and tongue.

About 90 years ago Eberle reported a personal experience in which saliva had toxic effects and was dependent upon emotional conditions. As a matter of fact, this theory was probably first suggested by Galen. Several workers, including Pasteur (1881), isolated many pathogenic organisms from the saliva. Many workers have described a number of strains of bacteria which were not pathogenic but were found to grow in oral secretions. Thomson and Thomson (1932) conclude, however, that: "There can hardly be any doubt that any poisonous effect of the saliva is likely to be due to its bacterial content rather than any chemical toxic substance present in it."

We know that the secretions of the glands of the mouth are under the control of "sympathetic and cranial nerves," and that nervous and psychic reactions materially influence these secretions. Kuster (1913) states that the secretions of the salivary glands in healthy persons has either a neutral or weakly alkaline reaction but it does become weakly acid in some of the constitutional disturbances. He also states that various reactions may be obtained from different parts of the mouth. For example, under certain conditions the moist tongue may be weakly alkaline while the interdental spaces and crypts of the mucous membrane are acid. Bloomfield and Huck (1920) carried out some hydrogen-ion concentration measurements and found that freshly expectorated saliva from normal persons gave a reaction varying from pH 6.0 to 7.5 with 80% of the specimens falling between pH 6.6 and 7.1. The reaction varied in the same individual at different times without any relation to the time of the day or the digestion of food or fluids. The use of mouth washes such as Dobell's solution caused a change in reaction of the saliva for about 30 minutes only and the internal administration of acids and alkalis did not alter the reaction in the least. There is no definite change in the hydrogen-ion concentration of the saliva in patients suffering from certain diseases. Marshall (1924) found the reaction of the saliva followed the buffer contents of the blood.

Florain and Sanarelli (1913) carried out experiments on filtered germ free human saliva and found it not only a poor culture medium but slightly inhibitory to bacterial growth. Kuster explained the story so frequently told about the dog that licks its wounded foot. It is thought that the saliva possesses some antiseptic value and for that reason the wound on the dog's foot heals rapidly when it is licked. He states that many of the dogs die from such wounds even though they are bathed in saliva frequently during the process of licking. On the other hand, when a dog licks a wound he not only mechanically cleanses it but also promotes free drainage and produces marked counter-irritation which aids the healing process even though the saliva has not antiseptic value. We may,

therefore, conclude that saliva has not been proven to possess chemical antiseptic properties.

### AUTHORS' STUDIES

Experiments were carried out in our laboratory by Arnold, Ostrum, and Singer (1928) concerning the auto-sterilizing power of the mucous membrane of the nose. Bacteria placed upon the normal mucous membrane of the nose, for some reason, disappear within a relatively short time. Since that time the investigation has been carried out over most of the exposed surfaces of the body and we find a very complete protective mechanism in the form of a self-sterilizing power of the skin and some of the mucous membranes of the body. This same type of investigation was carried out within the oral cavity and we obtained some very interesting results.

Miller and Ryan (1932) working in our department on the economical and practical methods of sterilizing clinical thermometers for hospital practice, found that after the thermometer had been removed from the mouth and rolled over the surface of an agar plate, there was a narrow band of small white colonies 2-3 mm. wide extending along the path of the thermometer. This zone was close to the protruding free end of the thermometer. Further investigation showed this band to correspond to the place where the lips were in contact with the glass. In many instances the only growth of bacteria was limited to this narrow area which was identified by an almost continuous band of colonies. These observations led us to make a more thorough study of the lip regions.

Our preliminary studies soon indicated that definite anatomical areas had to be chosen and individual observations made of each region. We, therefore, divided the mucous surface of the mouth into (Fig. 1):

Region 1. The skin surface immediately below the junction of the skin and mucous membrane of the lower lip.

Region 2. The junction of the skin and the mucous membrane of the lower lip.

Region 3. The moist zone of the lower lip which meets the upper lip.

Region 4. The midline of the lips.

Region 5. The junction of the mucous membrane and the skin of the upper lip.

Region 6. The moist zone of the upper lip which meets the lower lip.

Region 7. The corners of the mouth.

Region 8. The vestibule of the mouth.

Region 9. The labial surface of the lower gums.

Region 10. The lingual surface of the lower gums.

Region 11. The frenulum of the tongue.

Region 12. The tip of the tongue.

Region 13. The midline of the tongue.

Region 14. The side of the tongue.

Region 15. The dorsum of the tongue.

Region 16. The base of the tongue.

Region 17. The mucous surface of the cheek.

Region 18. The anterior pillar.

Region 19. The hard palate.

We first studied the endogenous flora of these areas by moistening sterile cotton swabs in normal saline solution which were brushed over the mucous membranes and then seeded upon plain agar plates. Our first purpose was to learn the relative density of the bacterial population residing on the surfaces of the areas under investigation. We performed about 100 such experiments; the averages from this number of

seedings are given as the final result obtained. Several hundred cultures were made.

The areas of the lips showed smaller colonies than those taken from elsewhere in the mouth. The order of predominance were: *Staphylococcus aureus*, *Staphylococcus citreus*, and *Staphylococcus albus*. Blood agar plates showed *staphylococcus* and *Streptococcus hemolyticus* occurred at the corners of the mouth, on the midline of the lips, and the tip of the tongue. The heaviest growths were obtained from the narrow zone of contact of the upper and lower lips, the side, dorsum, and base of the tongue, the surface of the cheeks, the anterior pillar, and the palate. The relative density of bacterial flora was found as follows: the midline of the tongue, tip of the tongue, lingual surface of the lower gums, corners of the mouth, midline of the lips, moist zone of the lower lip which meets the upper lip, the vestibule of the mouth, the labial surface of the lower gums, but the junction of the mucous membrane of the lower lip and the skin was almost sterile and we found no growth at all over the frenulum of the tongue.

Our next investigation was directed toward studying the auto-sterilizing power of the mucous membranes of the mouth and also the highways which are used by the transient bacteria. The same technic was carried out in this problem as was used in studying the auto-sterilizing power of the skin. This consisted of washing off the *Bacillus prodigiosus* growth on a

Fig. 1

plain agar plate with 10 cc. of saline, and diluting this with normal saline solution 1 to 100,000. A sterile cotton swab was saturated in this solution and a plain agar plate was seeded from this swab as a control. To avoid the mechanical removal by oral secretions a double saliva ejector was held in the mouth while a saturated sterile cotton swab, as above, was used to seed *Bacillus prodigiosus* organisms upon the area under investigation. Other sterile cotton swabs were brushed over different but adjoining areas on the region at five minute intervals and plates were inoculated with these swabs. We frequently waited two or three days before reading the plates to allow the full pigmentation of colonies to develop.

The first area to be studied was the labial surface of the lower gums near the gingivus. The results obtained over a period of 40 minutes showed practically no disappearance of the *Bacillus prodigiosus* organisms from this area. That is to say that here is an area where there is little or no auto-sterilizing power of the mucous membrane. Bacteria seeded upon this area may remain unchanged, except for mechanical removal, for a relatively long time and if these were pathogenic bacteria they would still be able to produce diseases. The experiment was repeated and the mouth was allowed to assume as normal movements as possible but our findings were so varied that we are unable to give a definite group of figures. This does tend to show, however, that the mechanical movements of the mouth markedly influence the removal of bacteria.

The next area investigated was the side of the tongue with the same technic and the use of the double saliva ejector. On this area we found a marked decrease in the number of bacteria grown on the plates which were seeded from the region over a period of 40 minutes. With 313 colonies on our control we found at the end of the first five minutes 246 colonies and only 56 colonies at the end of 40 minutes. We may conclude that the side of the tongue is capable of destroying bacteria without the aid of any washes, antiseptics, or brushes.

The usual technic was again used in studying the mucous membrane of the cheek. The control showed 414 colonies. At the end of five minutes the plates gave a reading of 138 colonies and at the end of the 40 minutes only 9 colonies were grown. It is evident that the cheek too may sterilize itself. These figures were so striking that we considered the flow of secretions of the parotid gland down the cheek as a possible source of error. We, therefore, placed a canula in Stenson's duct in order to completely control the flow of saliva. Upon repeating the experiment under these conditions we obtained results which substantiate those of the previous experiment and again proved the self-sterilizing power of the mucous membrane of the cheek.

We then turned our attention to the pathways over which the transient bacteria travel as they pass backward from the lips over the dorsum of the tongue to the throat. We divided each lateral half of the dorsum of the tongue into three equal longitudinal parts. A suspension of *Bacillus prodigiosus* was swabbed upon each area and plates were seeded from these zones by swabs taken at five minute intervals. The double saliva ejector was used and the tongue was held in a fixed position. The results were much the same as those obtained from the gingival margin which showed relatively little if any disappearance of bacteria.

A suspension was then swabbed on the lips and the normal movements of the mouth were permitted as nearly as possible. The lips were licked in the usual manner and swabs taken not only from each of the three zones but from adjoining fields at three minute intervals and each specimen was seeded on a plain agar plate. The results were not so constant as we should have liked but an analysis of the colony count proved that the highways by which bacteria travel toward the throat is approximately the middle third of each lateral half of the dorsum of the tongue. The tip of the tongue was surprisingly free from test bacteria but there was an area on the margin about  $1\frac{1}{2}$  cm. lateral to the midline over which the bacteria passed in the beginning of their travel backward. The speed with which the organisms move seems to be in relation to the firmness with which the tongue is pressed against the palate and the amount of suction produced. The average movements of the bacteria in a backward direction is very rapid. At times *Bacillus prodigiosus* were found at the base of the tongue in the first three minute interval after licking the lips.

### DISCUSSION

When we consider the bacterial flora of the oral cavity we must think of two distinct groups of organisms: the intrinsic or endogenous, and the transient or exogenous flora. The intrinsic flora is made up of those organisms which have become attached to the cells, are between the papillae, in the crypts and may be found in the openings of the ducts of the glands. These organisms do not produce disease and may be considered as the normal flora. Their purpose is not definitely known but they persist regardless of the most radical methods used to remove them.

The transient or exogenous group of bacteria are those organisms which are introduced into the mouth not only by the air, food, and water, but also by the licking of the lips which have become contaminated from eating utensils, public drinking cups or fountains, etc. These transient bacteria travel backward toward the throat at a rapid rate which is in proportion to the amount of suction produced when the tongue is pressed firmly against the palate. In some cases only two or three minutes is required for an organism to pass from the lips to the base of the tongue and throat. These are the bacteria which are foreign to the individual and if no resistance has been developed against them they are the organisms which are capable under certain conditions of producing disease. We were unable to find evidences of bacteria passing from the throat into the mouth.

The mechanical removal of bacteria and the auto-sterilizing mechanism of the mucous membrane of the oral cavity are the most important factors in the elimination of bacteria from the mouth. The saliva is neither a good culture medium for bacteria nor does it possess antiseptic properties. As the saliva is stirred up by the movements of the tongue and cheeks it materially assists in the mechanical removal of bacteria from the many fields within the oral cavity. The hydrogen-ion concentration of the saliva is in direct proportion to the buffer content of the blood, as well as the carbon dioxide tension of the expired air, and although it does vary within wide limits under normal conditions there is nothing which may be used locally or by internal medication that will change the reaction for more than a few minutes at a time.

Diet has little if any influence upon the reaction of the saliva or upon the bacterial flora of the mouth. Oral hygienic procedures consist primarily of cleansing the mouth of food debris and brushing foreign materials from the surfaces of the teeth, but antiseptic mouth washes are of little value except as a mechanical factor in the removal of bacteria, the same as sterile water.

The self-sterilizing power of the mucous membrane of the mouth is one of our most important protective mechanisms against bacterial invasion by the transient group of organisms. The highways over which these transient organisms pass is rather limited to the middle longitudinal third of the dorsum of the tongue. The cheeks, side and frenulum of the tongue maintain a very perfect auto-sterilizing mechanism but the surface of the gums near the gingival margin,

the dorsum of the tongue, and the palate show little ability to destroy bacteria.

The lips are apparently a primary seeding zone for the mouth. The narrow zone of contact of the lips is an area which, when inoculated with organisms, seems to furnish an unlimited supply for almost continuous contamination of the oral cavity. It is evident that chronic infections of the mouth call for a close inspection and examination of not only the gums, interdental spaces and dorsum of the tongue but also the mucosa of the lips.

The investigations of the bacterial flora of the mouth have made little progress over a long period of time but now that we are beginning to understand the normal physiological processes which are going on in the oral cavity we expect the problems will unfold themselves in the future.

## Gastroscopy: Past, Present and Future

By

EDWIN BOROS, M.D.,\*  
NEW YORK CITY, NEW YORK

SINCE the origin of the concept of the direct inspection of the stomach through the use of an orally introduced instrument by Kussmaul, there have arisen workers, from time to time, whose labors and enthusiasm in this field have furthered such a procedure, as an advancement in the diagnosis of diseases of the stomach. Amongst these pioneers in this new approach, there may be mentioned Nitze, Mikulicz, Rosenheim, Kelling, Loening and Stieda, Sussman, Elsner, Schindler and Jackson, in this country.

During this era of development, suggestions for various methods of exploration in this fashion, supplemented by the addition of newer and improved instruments which were more likely to facilitate and establish this method as a safe and reliable procedure, were undertaken and practised. Despite disappoint-

ments and obstacles, the enthusiasts in this work clung to the hope and expectation that the innermost recesses of this wholly unexplored viscus would be amenable to exploration, and result in the establishment of an acceptable aid to our diagnostic and therapeutic armamentarium.

It might be mentioned, that, not without warranted distrust and condemnation, efforts in this direction were subjected to considerable criticism, for the instruments consisted of rigid tubes for the most part, of a character which did not require much exertion to do damage and to endanger the patient; frequently the results were alarming. Furthermore, the ordeal of the introduction, the oft adverse reaction of the patient, all this did not serve particularly to enhance the general acceptance of gastroscopy as a routine procedure of examination. It might be emphasized, that the re-

\*Associate Gastroenterologist to the Bronx Hospital.  
Submitted April 16, 1935.

sults of the examinations already conducted, bearing in mind the limited visibility of a considerable portion of the gastric mucosa to the examining eye, served to occasion doubt and distrust not only as to the actual value of the procedure but to its practicability as well.

Nevertheless, it is phenomenal, and one cannot help but marvel at the enormous skill and dexterity with which this seemingly dangerous introduction of the rigid tube into the stomach, was and is still being practised without ill effects to the patient. Recognition soon gained ground, that if the arguments of the opposition were to be met, that a way must be found which would allay the fears already noted. Accordingly, a flexible apparatus was evolved, in the expectation that this type of gastroscope would eliminate the dangers experienced with the introduction of the rigid tubes. This type of instrument was however, not without fault. It remained for Rudolf Schindler to develop the present model, which is a combination of a semi-flexible and rigid tube, encasing a lens system for observation. The angle of vision of this new instrument is 60 degrees, and enables the examiner to explore the greater portion of the stomach, inclusive of the pylorus and cardia. The length of this gastroscope is 68 cm. without its rubber attachment.

At the present time, we are using the Wolf-Schindler gastroscope. We are convinced that the objections of the many antagonists to the rigid tube gastroscopy have been overcome. Needless to state, there are definite contraindications to the introduction of the Schindler improved apparatus, which cautions must be fully and at all times observed if one is to avoid accidents to the patient. Further, one must not expect this method of examination to displace those means which we already have at our disposal for the evaluation of the many problems present in the diagnosis of gastric disease. Gastroscopy is meant to *supplement*, not *supplant* the usual physical, chemical and roentgenological examinations of the patient.

It is to be remembered, that in gastroscopy, the *positive* findings are of importance. A negative examination by no means precludes the possibility of an undetermined lesion, any more than occurs in the course of a roentgenologic examination of a patient, and of course, this element is to be appraised in the light of the skill and experience of the gastroscopist, as well as in the recognition that all areas of the gastric mucosa are not discernible. It might be well to mention here, that in order to limit the unexplorable areas of vision of the gastric mucosa, it is advisable to have recourse to both types of gastroscope, the straight and the curved tipped instruments. The proper selection of either of these instruments will tend to reduce errors to a minimum.

In contrast to the open tube, the Wolf-Schindler system confines the examiner to the inspection of the interior of the stomach. Whereas an opportunity is afforded to *study* lesions and diseases in various stages of development and progress, to note properties and characteristics of different processes, degrees of healing and advance or retrogression in the course of a gastric affection, yet the removal of tissues for microscopic examination, instrumentation or possible topical applications for therapeutic purposes is possible only by means of the open tube. Observation through the closed tube gastroscope permits at the present time study and recognition of the early manifestations of local or systemic diseases, helps to differentiate lesions of a doubtful nature by actual visualization, enables one to note changes in form and function in a manner hitherto impossible and permits observations as to the course and duration of disease as well as the effects of therapeutics.

As for the possibilities: it needs but little emphasis to remind one of the vast prospects, not only in the evaluation of those conditions already known to us, but also in a field where knowledge may be enriched and new vistas and promises of greater satisfaction afforded as new revelations unfold themselves.

## A New Tube For Anaesthetization of the Hypopharynx

By

RUDOLF SCHINDLER, M.D.\*  
CHICAGO, ILLINOIS

---

IT is customary to anaesthetize the throat before executing an esophagoscopy or a gastroscopy. There are some authors who have not found it necessary. It certainly renders the procedure less disagreeable, and in my experience has been found to be of distinct advantage.

In anaesthetizing the hypopharynx, it is necessary to introduce an anaesthetic on an applicator beyond the *musculus constrictor pharyngis*. This procedure can be extremely difficult in some patients, due apparently to spasm of the constrictor muscles of the pharynx. Some patients contract their muscles convulsively when a hard metal applicator is introduced into

the pharynx, whereas a simple rubber tube can usually be passed without difficulty. Much patience and ingenuity are often necessary at this stage. Therefore the author has always emphasized that this can be the most difficult part of the entire endoscopic examination. On one occasion in his experience an accident occurred in which, as a result of the resistance of the patient, the cotton became separated from the applicator, allowing its sharp point to inflict trauma in the upper esophagus, which was followed by an abscess.

Therefore it seemed necessary to devise a different method for anaesthetizing the hypopharynx. The fact that even the most resistant patient swallows the soft rubber tube easily suggested the possibility of using

\*Visiting Professor of Medicine, University of Chicago, Chicago, Illinois.  
Submitted May 14, 1935.

such a tube with holes cut in the walls. This was not entirely satisfactory, for when the anaesthetic liquid was injected through such a tube, it flowed out through the upper holes only and the desired effect was not ob-

withdrawn. The type of local anaesthetic used is important. Cocaine should not be chosen because it is toxic. Most of the other substitutes do not have an adequate anaesthetizing effect. Moutier, however, ad-

Fig. 1. Photograph of Anaesthetization Tube.

Fig. 2. Diagram illustrating construction of anaesthetization tube.

tained. A better result was secured by filling the tube with cotton.

This led to the construction of a rubber tube containing a number of smaller tubes, each opening through the walls of the outer tube. The upper end of the large tube carries a metal connection for the insertion of the syringe. (Figs. 1 and 2).

By this construction the anaesthetization of the hypopharynx is now greatly facilitated. The patient swallows the tube, the anaesthetic fluid is injected with a syringe through the tube, and the tube is then

withdrawn. The type of local anaesthetic used is important. Cocaine should not be chosen because it is toxic. Most of the other substitutes do not have an adequate anaesthetizing effect. Moutier, however, ad-

vises the use of a 10% solution of "Delcaine". I have found a 2% solution of "Pantocaine" very satisfactory. Five cubic centimeters of this 2% solution are injected through the tube as described. It is advisable to repeat the procedure after five minutes. Then the mucosa is insensitive.

As a result of this procedure the danger of trauma in the anaesthetization of the pharynx has been eliminated. This renders the entire endoscopic examination much less uncomfortable, and considerably shortens its duration.

## ABSTRACTS

YEGGE, W. BERNARD.

*A Critical Review and Evaluation of Tests for Liver Function. Ann. Int. Med., VIII, 907, February, 1935.*

The author prefaces his article with some reminders of physiological fundamentals, such as the functions of the liver and a statement that a large amount of structural change may obtain before functional disorders are in evidence, and its contrary corollary, that a marked alteration in function may obtain without any structural change. He follows a plan adopted by most of the recent authors in considering the various tests under headings of liver function, but cautions that while many tests for separate functions of the liver have been devised, none has been advanced that will evaluate these functions as a whole, hence it is necessary to study these functions separately.

*Cholecystography* is looked upon as a method of differentiation between gall bladder and liver disease, rather than having a bearing as a test for liver function. Of *transduodenal drainage* procedure he says that the microscopic study of bile obtained by duodenal drainage is important, as it may reveal evidence of definite infection or of crystals of cholesterol or calcium butyrate, which are important in the diagnosis of cholecystic disease. He stresses the importance of an estimation of the *bilirubin* and thinks of the *icterus index* as the simplest method. He calls attention to its importance in subclinical jaundice, but cautions that in chronic liver disease it is of

little value except to follow the course of the disease and to detect the early onset of jaundice. In referring to the *van den Bergh test*, attention is called to the recent findings of Jacobi, which indicate that the plasma and the serum may be used with equal accuracy in the determination of bilirubin. Special emphasis is laid on the so-called diphasic reaction of the van den Bergh, which may be found in toxic or infectious jaundice, and in hemolytic jaundice, when the increased viscosity of the bile may result in blockage of bile capillaries in both forms of bilirubin in the blood. Laboratory data covering a *destruction of red blood cells* is not considered a test of liver function, but rather one of hemolytic jaundice, since this function is shared by other organs of the body through the reticulo-endothelial system. He thinks the determination of the *coagulation time* of the blood is a very important test of function of the liver, since when the liver is damaged to any extent, the blood fibrinogen is increased and the clotting time of the blood is increased. The *sedimentation test* is considered very useful in conjunction with the coagulation test in order to detect the hemorrhagic tendency. Some attention is given to a test for determination of *fat metabolism*, and Whipple's method is advised, but he concludes this phase of the subject by stating that he has not had enough experience with estimations of blood lipase to give an opinion as to its value. The *hemoclastic crisis test* has very little value, he thinks, in the diagnosis

of liver disease, since other factors beside liver damage cause a variation in the leucocyte count and the other phenomena. Conceding the determinations of uric acid as a valuable means of studying liver function in dogs, he thinks that it has not been proven of value in humans, due to the fact that large injections of uric acid may cause lesions in the kidneys. Of a determination of guanadin in the blood, he says that while it is increased in patients with acute arsphenamine hepatitis, acute catarrhal jaundice and predisposition to toxemia and eclampsia, there is no deviation from the normal blood guanadin in chronic liver diseases such as carcinoma, syphilitic hepatitis, alcoholic cirrhosis and obstructive jaundice. In determining impairment of liver function in the role of carbohydrate metabolism, he favors the galactose test. Elimination of any amount over 3 grams of galactose in five hours is considered as an evidence of hepatic impairment. Attention is invited to the fact that in obstructive jaundice without liver damage and in hemolytic jaundice the readings are normal.

No definite conclusions are expressed from the Author's experience with tests to determine the antitoxic and protective functions of the liver, but speaks hopefully of the possibilities for future study. The Bromsulphthalein test detects the impairment of liver function as frequently as any other test, and this when done along with an icterus index determination, most frequently agrees with the clinical picture.

Virgil E. Simpson, Louisville.

THORSNESS, D.T., M.D.

*The Bacteriology of Cholecystitis; the virulence and spore formation of Clostridium Welchii. S., G. and O., Vol. 59, No. 5, Nov., 1934, pp. 752-756.*

In a bacteriological study of the walls of surgically excised gall bladders in 75 cases, the following results were found: In 30 cases, the sections were sterile; streptococci were found in 13 cases, staphylococci in 26, bacillus coli in 6, diphtheroids in 5, and Clostridium Welchii in 5.

In human bile, 59 cases were studied. In 50 it was sterile, streptococci were found in 7, staphylococci in 1, bacillus coli in 1, bacillus subtilis in 1, and Clostridium Welchii in 1. In 25 cases of gall stones in man, the concretions were sterile in 15 cases, streptococci were found in 5, staphylococci in 3, bacillus coli in 4, bacillus subtilis in 1, and bacillus pyocyaneus in 1.

Clostridium Welchii found in gall bladders usually come from the intestinal tract and reach the gall bladder through the portal system or by ascending through the duct. The author feels as the result of the studies which he has carried out, that this organism is in the nature of a secondary invader and seldom is found to be the primary cause of cholecystitis. It is also shown that a healthy person is able to reduce Clostridium Welchii to a state of low virulence as well as inability to form spores and for the maintenance of virulence and spore forming ability of this organism in vivo, there must be a marked lowering of tissue resistance.

N. W. Swinton, Boston.

RIVERS, A. B.

*Pain in Benign Ulcers of Esophagus, Stomach and Small Intestine. J.A.M.A. 104:169 (Jan. 19, 1935.)*

This study concerns itself primarily with the pain mechanism in patients with peptic ulcers. The clean cut syndrome of peptic ulcer is diagnostic of uncomplicated peptic ulcer. When a peptic ulcer invades different depths of tissue or neighboring organs complicated symptoms develop. In the material used only such cases were accepted in which direct inspection of tissues and exact information from the history were obtainable.

In the esophageal ulcer group, the ulcers were situated just above the cardia. The pain was present and intensified by deglutition.

In more than 90 percent of patients with shallow gastric ulcers the pain was poorly localizable. Large ulcers or subacute inflamed ulcers gave definite pain localization in half of the cases.

Perforating gastric ulcers in 90 per cent of the cases gave accurately localizable pain in the left upper quadrant.

Obstructing duodenal ulcers produce diffuse epigastric distress. In 90 percent of perforating duodenal ulcers the pain is localized with accuracy to the right upper abdominal quadrant.

In shallow ulcers in or about a gastro-enteric stoma the pain is poorly localizable. Perforating ulcers involving a gastro-enteric stoma produced definitely localizable pain. Perforating jejunal ulcers in 96 percent of cases caused a downward or posterior projection of that pain.

Francis D. Murphy, Milwaukee.

PORTIS, SIDNEY A., AND GROVE, J. C.

*The Gastro-Intestinal Manifestations of Urologic Disease. J.A.M.A. 104:710 (Mar. 2, 1935).*

The close anatomic relationship of the kidneys with other abdominal viscera and because of the inter-relationship of the nerve supply of the upper urinary tract and the organs of digestion, the gastro-enterologist should be prepared to discover pathological processes in the urinary tract in individuals having gastro-intestinal complaints without pathology in this tract. Especially important is the fact that although the history may reveal some urinary difficulty frequently it does not. The authors report a group of thirty patients of this type. Detailed discussion of nine of the cases is given.

The authors emphasize that in any obscure gastro-intestinal complaint the urological tract should be carefully investigated. In many of these cases the investigation will be rewarded by definite findings, which may then be treated with benefit to the patient.

Francis D. Murphy, Milwaukee.

JACKSON, CHEVALIER, AND JACKSON, CHEVALIER L.

*Peroral Gastroscopy, Including Examination of the Supradiaphragmatic Stomach. J.A.M.A. 104:269 (Jan. 26, 1935).*

The authors discuss the three methods of gastroscopy namely the open tube, a lens system and a combination of the open tube and lens system.

The open tube is the method required for the removal of foreign bodies and the taking of specimens for histologic study. Its limitations are that it requires a straight and rigid tube, much training and skill in the introduction of the instrument and a limited explorable area.

The advantage of a lens system is that layer field of vision is available. The limitation to its use is the danger of the introduction of an instrument presenting no esophageal lumen ahead. This danger is overcome by the introduction of an open tube through which a lens system is passed.

The authors describe the normal colon, form and movements seen through the gastroscope in the esophagus and stomach.

The authors state that every patient with gastric symptoms should have a gastroscopic examination for diagnosis unless there are serious contraindications. Hematemesis, chronic gastritis, diagnosed by gastroscopy in addition to all other established diagnostic aids.

Foreign bodies that are too large to pass thru a normal or a small pylorus, or of such character as to render its passage through the intestine dangerous, should be removed by peroral gastroscopy.

In gastritis and in examination of the supradiaphragmatic stomach gastroscopy is of value.

In diagnosis of new growths and in the obtaining of biopsy specimens gastroscopy has proven valuable and free from danger.

Francis D. Murphy, Milwaukee.

## SECTION II—*Experimental Physiology*

### A Symposium Concerned with the Duodenal Factors in the Neutralization of Acid Chyme\*

By

FRANK C. MANN, M.D.,

and

JESSE L. BOLLMAN, M.D.

ROCHESTER, MINNESOTA

THE following series of papers is offered as a contribution to the problem of the physiologic mechanisms by which the normal reaction of the duodenum is maintained. Our interest in this subject has developed from our studies of experimentally produced peptic ulcer in which it appears that exposure of the intestinal mucosa to unneutralized acid for a longer period than occurs normally is a major factor in the development and maintenance of chronic peptic ulcer. In these experiments no definite increase in gastric acidity can be demonstrated, but duodenal or gastrojejunal ulcer develops following interference with the alkaline secretions of the duodenum, liver, or pancreas. These three alkalizing secretions represent the main protection of the gastro-intestinal tract against the formation of ulcer.

We would sharply differentiate two types of experimentally produced ulcerations of the gastric and intestinal mucosa. The one type of multiple hemorrhagic erosions of the mucosal surface, such as is often seen in the gastritis of terminal uremia and other toxic conditions, has been produced experimentally by various procedures. One of us described such ulcers that occur following removal of both suprarenal glands (4). Durante has described similar lesions which occur following section of the splanchnic nerves. Similar lesions have been produced by injection of diphtheria toxin and other bacterial products, after the administration of certain drugs, and by a large number of other methods. Unless death intervenes, these lesions heal promptly and completely and do not develop into lesions which resemble chronic peptic ulcers. The experimentally produced lesions that develop into peptic ulcers, which are grossly and microscopically similar to peptic ulcers as seen in man, are quite different from this acute hemorrhagic type of erosion.

The type of lesion that resembles true peptic ulcers, which is usually single and always few in number, was produced by Exalto, by Mann and Williamson and others, particularly by Matthews and Dragstedt and Weiss, by draining the duodenal content into the term-

inal portion of the ileum. Typical gastrojejunal ulcers developed after this procedure at the site where the gastric content first impinged on the jejunal mucosa. This lesion was of the perforating type, beginning with a pale, saucer-like erosion of the surface of the mucosa and gradually becoming deeper until it appeared indistinguishable from peptic ulcers as seen in man. Many subsequent methods of development of experimental peptic ulcer have been devised with this principle of surgical removal of some of the alkalizing influences of the duodenum (3).

All of these methods of forming ulcer indicate that there are at least three factors of importance in producing peptic ulcer. The acid factor appears most important. Exposure of the mucosa to unneutralized acid over a longer period than occurs normally results in the formation of ulcer and prevents the healing of the lesion. Interference with or failure of the neutralizing mechanisms appears to be of primary importance in the causation of these lesions. Mechanical factors, such as the direction of force of the contracting stomach, seem to determine the site of formation of ulcer. The individual resistance of the various tissues to the formation of ulcer also determines the situation of the experimental ulcer. The fundus of the stomach is more resistant to ulcer formation than is the pyloric mucosa, the duodenum is less resistant, and resistance decreases in the small intestine with the distance from the pylorus. Thus the formation of ulcer in these experiments appears to be the result of the amount of exposure to acid, the resistance of the tissue exposed to the acid, and of mechanical factors. Constitutional factors in formation of the ulcer are suggested by certain experiments, but these may be a part of the acid and mechanical factors. In the experiments of surgical drainage of the duodenum, the constitutional factor appears slight, since healing of the peptic ulcer occurs following surgical protection of the ulcerated area from the acid and mechanical factors, and a new ulcer will develop at a new site exposed to these two factors.

Our first attempts to study the secretions of the duodenum failed to give us data of physiologic importance. For the most part our failures were due to the

\*Division of Experimental Medicine, The Mayo Foundation.  
Submitted May 12, 1935.

development of duodenal fistulas which rapidly produced symptoms like those of high intestinal obstruction (8). Undoubtedly most of the changes in the reaction of the duodenum that we observed were the results of loss of duodenal content and could not be considered physiologic. However, we were able to develop a method of producing a duodenal fistula which did not leak and through which small samples of duodenal content could be removed at intervals with no physiologic disturbance (6). One animal with such a duodenal fistula has been in the laboratory for six years and has always been in excellent condition. With this type of fistula, subsequent operations could be performed, so that the duodenum could be isolated from the remaining portion of the gastro-intestinal tract and the biliary and pancreatic ducts transplanted or isolated. The following studies of the neutralizing effects of the duodenal secretions were made with modifications of this method.

Several facts are established from the results of these studies. Whereas the reaction of the content of isolated duodenum remains remarkably constant, that of the intact duodenum, particularly the first few centimeters, undergoes marked fluctuations. This site where duodenal ulcer develops is the chemical battleground of the gastro-intestinal tract. It is clearly established that the duodenal secretions make the duodenal content capable of neutralizing more acid than

is presented to it under physiologic conditions. The pancreatic secretion is the most important of the three secretions in maintaining the normal reaction of the duodenal content. Diversion of bile from the duodenum has practically no effect on neutralization of the acid chyme, and its effect on the reaction of the duodenal content is probably mainly due to dilution. Elimination of the pancreatic secretion from the duodenum has a slight, but under certain conditions a definite, effect on the neutralization of the gastric content passed into the duodenum. It is apparent that the normal duodenum has marked powers of compensation for the loss of one of its secretions.

We have always been impressed with the remarkable power of the stomach and the duodenum to compensate for marked alterations in their secretory mechanisms. While we have emphasized the capacity of the normal duodenum to neutralize the acids that reach it from the stomach, thus permitting an almost unvarying reaction of the content of the jejunum and ileum, it should be noted that this capacity is definitely limited, as evidenced by the increased acidity of the duodenal content following a protein meal, which is further enhanced after elimination of the secretion of the pancreas. It also appears significant that resistance to the formation of ulcer is decreased in proportion to the interference with the alkalizing mechanism of the duodenum.

## The Reaction of the Content of the Isolated Duodenum\*

By

PAT R. IMES, M.D.\*\*

ROCHESTER, MINNESOTA

THAT the secretions poured into the duodenum are normally alkaline or neutral in reaction and serve to neutralize, buffer, or dilute the acid chyme has long been recognized. In recent years alkalinity and neutralization have been accurately demonstrated in man as well as in animals. The duodenal content of the former is easily obtained through the Rehfuß tube. Experimentally, however, it has been found more advantageous to obtain the content through fistulas draining externally. The duodenal content, as obtained in either manner, is obviously usually a mixture of

gastric secretion, food, and the secretions passed into the duodenum. Two of the secretions drained into the duodenum, bile and pancreatic juice, have been obtained separately by cannulating the bile and pancreatic ducts, respectively. Determinations of the hydrogen ion concentration and the buffer values of these two secretions have therefore been made (2). Figures are not available for the reaction of the duodenal content unmixed with the gastric content that passes the pylorus. The purpose of this investigation was to determine the changes in pH and buffering values of the duodenal content of the isolated duodenum.

In order to obtain the duodenal content under as nearly physiologic conditions as possible, duodenal fis-

Submitted May 12, 1935.

tulas were made in six healthy dogs using the transposed intestinal loop method (4). At a subsequent second-stage operation the stomach was separated from the duodenum and anastomosed to a loop of jejunum about 25 cm. from the closed end of the duodenum (Fig. 1). All operations were done with the animals under ether anesthesia and using surgical technic. Following this procedure samples of the content of the isolated duodenum were easily obtained and their hydrogen ion concentrations determined using the quinhydrone gold electrode. The buffering capa-

city of the duodenal content was also determined on the samples obtained from one of the animals. This was done by taking 2 cc. of the secretions and adding tenth-normal hydrochloric acid until the pH was reduced to from 3.5 to 4.0, which level represents the end point of dimethyl-amino-azobenzene as used in determining the free acidity of gastric secretions. Thus the degrees of alkalinity are analogous to the manner commonly used to express the acidity of the gastric secretions. The potentiometer was used to determine when that pH level was reached.

Fig. 1. Relative position of duodenal fistula and isolated duodenum.

city of the duodenal content was also determined on the samples obtained from one of the animals. This was done by taking 2 cc. of the secretions and adding tenth-normal hydrochloric acid until the pH was reduced to from 3.5 to 4.0, which level represents the end point of dimethyl-amino-azobenzene as used in determining the free acidity of gastric secretions. Thus the degrees of alkalinity are analogous to the manner commonly used to express the acidity of the gastric secretions. The potentiometer was used to determine when that pH level was reached.

Samples of the duodenal content were secured at half-hour intervals on animals during the fasting state and following the ingestion of the following standard meals: 100 gm. of lean horse meat, 200 gm. of lean horse meat, 100 gm. of lard mixed with 100 gm. of cracker meal, and 100 gm. of syrup mixed with 500 cc. of milk. Observations were made in two series, before and after isolating the duodenum.

### RESULTS

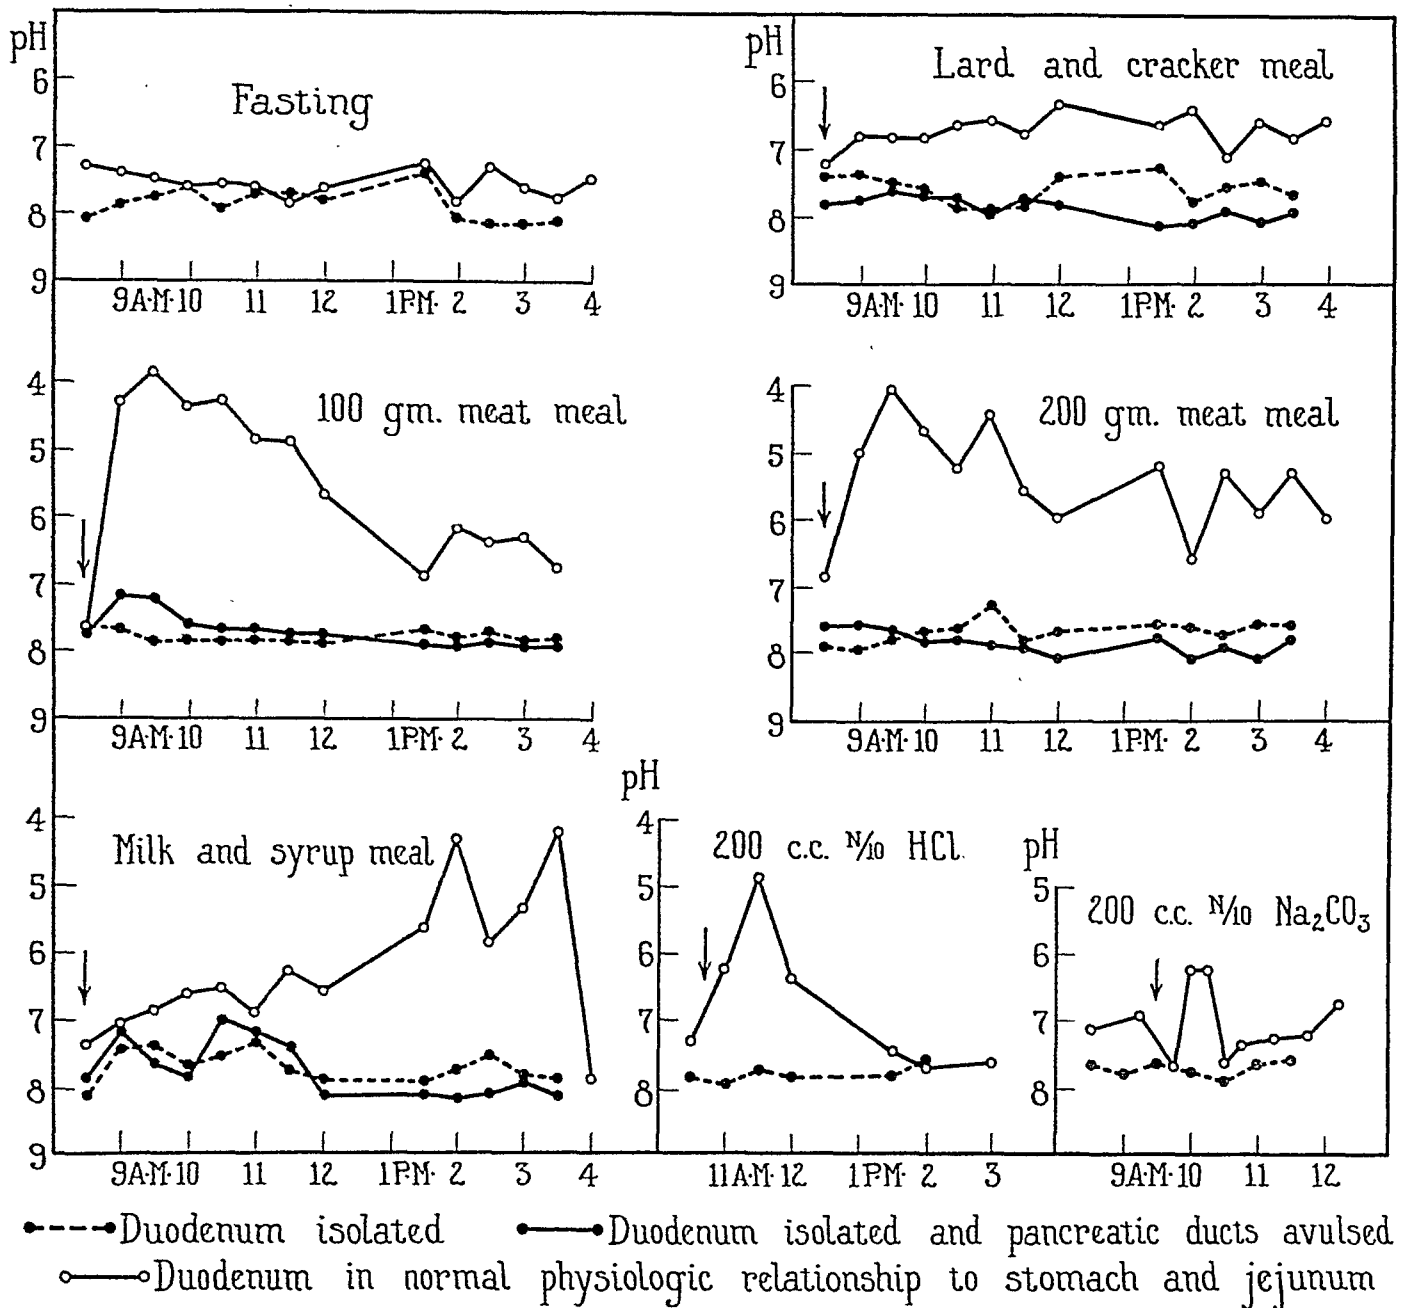

The first series of determinations on the duodenal content, with the duodenum in normal physiologic relationship to the stomach, confirm the results of Mann and Bollman (3) who worked under identical conditions and used a similar method. The reaction of the fasting content was regularly alkaline, the pH varying

from 7.00 to 7.88 except for an occasional sample as low as 5.64. Following test meals, the pH fell almost immediately and usually maintained a fairly characteristic curve throughout the eight-hour period of observation for each type of test diet. Following the fat meal, the pH was lowered to between 6.0 and 7.0 and maintained that level throughout except for an occasional sample from one of the animals which was as low as 2.0. A somewhat similar curve was obtained following a carbohydrate meal; however, in several instances, there was a definite tendency toward a de-

crease in the pH after a period of three or four hours following this meal, and that low level was maintained usually for the remainder of the period of observation. Following a protein meal, the samples were definitely more acid than with the other diets, the pH ranging between 3.5 and 5.0, with occasional variations between 2.2 and 6.75. That low level was maintained longer when feedings consisted of 200 gm. of raw meat than when only 100 gm. were given. Following the latter meal the pH began to approach the fasting level in five to six hours following feeding.

The second series of determinations, on the reaction of the content of the isolated duodenum composed of bile, pancreatic juice, and succus entericus, was made on samples obtained under conditions identical with the first. Regardless of the state of alimentation or the type of test diet used, the pH was remarkably constant and varied between 7.10 and 8.15 with few exceptions. Samples of the duodenal content following the administration of 200 cc. of tenth-normal hydrochloric acid and 200 cc. of tenth-normal sodium carbonate likewise showed no appreciable variation in the hydrogen ion concentration (Fig. 2).

The buffer values of the content of the isolated duodenum, however, showed marked variation, 40 to 95 points, and usually were directly proportional to the

pH of the original sample although frequently just the opposite was noted. Thus a sample with a pH of 8.0 might have 80 points (40 and 80 cc. of tenth-normal hydrochloric acid required to reduce the pH of 100 cc. of the secretions to 4.0). The state of alimentation and the various test diets had no constant effect on the buffer capacity of the samples of duodenal content. Two of the animals were given 1 mg. of histamine, which did not affect the pH or buffer capacity of the duodenal content; likewise, samples following the administration of 200 cc. of tenth-normal hydrochloric acid and 200 cc. of tenth-normal sodium carbonate showed no consistent changes.

The influence of the pancreatic secretion on the pH and buffer capacity of the content of the isolated duodenum was studied by evulsing the pancreatic ducts and comparing the determinations made before and

Fig. 2. Representative curves of pH of the content of the intact and isolated duodenum in the fasting state and following various test meals.

after evulsion. A study of the effect of this procedure on the content of the intact duodenum was made by Hoerner. Following evulsion of the pancreatic ducts, the pH of the duodenal content was essentially unchanged, the pH being 7.17 to 8.13 as compared to 7.0 to 8.15 before evulsion. The buffer values, however, were definitely reduced and amounted to approximately two-thirds of those before evulsion, an average of 37 points as compared with 60 points before evulsion (Fig. 3).

#### COMMENT

Much work has been done on the reaction of the content of the duodenum in its normal anatomic and physiologic relationship with the stomach, and some work has been done on the reaction of pancreatic and biliary secretions as obtained by draining externally through cannulas. However, this investigation had to

Fig. 3

do with the reaction and degree of alkalinity of the isolated duodenal content as a whole, when obtained under approximately physiologic conditions.

The constancy of the slightly alkaline reaction of the content of the isolated duodenum in contrast to the highly variable reaction of the gastric secretion is explained by the presence of weak alkalies, buffer substances, in the former. Consequently, determination of the pH alone gave no reliable indication as to the degree of the alkalinity, and the latter, as determined

Fig. 3. Curves illustrating the buffer capacity of various secretions obtained by adding tenth-normal hydrochloric acid to 2 cc. of the secretion in amounts as indicated.

by titration, was found to fluctuate in rather wide limits. This qualitative fluctuation is dependent on the relative proportion of pancreatic juice, bile, and duodenal secretion in a given sample and bears no relationship to the state of alimentation. There is, however, a quantitative relationship to the state of alimentation, which was only grossly observed, and no accurate estimation of the total amount of alkali secreted could be determined.

The degree of alkalinity of the combined duodenal secretions is equal to, and usually exceeds, the degree of acidity of the gastric secretions when expressed in terms of titration for equal amounts. Thus, the protective function of the duodenal secretions in preventing free hydrochloric acid from coming in contact with the small intestine is established in a concrete manner. Without this protection, McCann observed an increasing tendency to ulceration that was directly proportional to the alkaline deficit beyond the pylorus.

### SUMMARY

The reaction of the content of the isolated duodenum is alkaline, with a pH of from 7.10 to 8.15. The alkalinity is caused by weak alkalies or buffer substances which fluctuate quantitatively. This fluctuation in reaction of the duodenal content probably depends on the relative proportions of its major constituents: pancreatic juice, bile, and duodenal secretion. The pancreatic juice has approximately twice the alkalinity of the bile.

## The Capacity of the Duodenum to Neutralize, Buffer and to Dilute Acid\*

By

G. ARNOLD STEVENS, M.D.  
ROCHESTER, MINNESOTA

THERE have been numerous studies of the reaction and buffering capacity of the content of the intact duodenum. In these studies it obviously was not possible to quantitate the duodenal content in this respect because of the admixture of saliva, food, and gastric secretion entering the duodenum through the pylorus. On the other hand, similar investigations of

the isolated duodenum which obviate this error, performed in vitro, have been few, and quantitative determination of the capacity of such a duodenum in vivo has not been reported.

It was the object of this investigation to accomplish this in the following manner: Fistulous openings were established at each end of the duodenum of dogs. The duodenum was subsequently isolated, thus preventing the influx of gastric content. Hydrochloric acid, of a strength within physiologic limits, was passed into the upper opening and the pH of the con-

\*Abridgment of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Surgery. Fellow in Surgery, The Mayo Foundation, Rochester, Minnesota. Submitted, May 12, 1935.

tent obtained from the caudal fistula determined. This procedure was carried out before and after isolation of the duodenum, in the fasting state and after the ingestion of various diets. From the data obtained it was possible to estimate the maximal capacity of the duodenum to neutralize, buffer, and dilute the acid introduced through the fistula and to suggest a relationship between the amount of acid normally passing through the pylorus and this capacity of the duodenum.

### REVIEW OF LITERATURE

Reports of the reaction of the duodenal content as a whole have not been in accord. McClendon and others believed that variations in types of indicators and attempts to harmonize results in vivo and in vitro are largely responsible for erroneous deductions. Mann and Bollman (12), using a transposed loop of intestine in making the fistula and the electrometric method of hydrogen ion determination, found values that

sodium, potassium, and calcium. They found that chloride ion, bicarbonate ion, and a trace of phosphate constituted the acid factors. Jones, Apperly, and others stated that the essential alkali of the pancreatic juice and bile is sodium bicarbonate, values being quoted of 0.65 per cent for the former and 0.2 per cent for the latter. Howell remarked that the alkaline reaction of the succus entericus is due to this salt.

Boyden and Birch attempted to ascertain in some measure the neutralizing power of the duodenal content of man. They found that various amounts of acid of physiologic strengths introduced through the Reh-fuss tube were neutralized in four to sixteen minutes. Spontaneous spurts of acid as a result of opening of the pylorus were said to be neutralized in thirteen minutes.

### METHOD OF INVESTIGATION

This investigation was conducted with seven healthy dogs weighing from 8.1 to 21.8 kg.

Fig. 1. Method of administration and collection of solutions exposed to duodenal action. The neutralizing power indicates the volume of hydrochloric acid that may be introduced into the duodenum in two hours without changing the pH of the fluid from the distal end of the duodenum.

seemed representative of results of the more recent workers. The pH of the content of the duodenum of the fasting dog averaged 7.6, with occasional fluctuations from 5.6 to 2. After a meal, the pH of the duodenal content paralleled that of the gastric content and usually did not return to the average fasting level of 7.6 for six hours postprandially.

Results of studies of the buffer values of the duodenal content have varied. McClure, Montague, and Campbell found that 140 to 392 cc. of tenth-normal acid or alkali were required to bring 1,000 cc. of duodenal content to the neutral point. Jones observed that 1 to 6 cc. of tenth-normal hydrochloric acid would bring the reaction of 10 cc. of bile or pancreatic juice to a pH of 7.00.

Gamble and McIver (5) determined that the fixed base of the pancreatic juice consists essentially of

Operative procedures were accomplished in two stages: The first stage (Fig. 1) consisted of making two intestinal fistulas of the transposed intestinal loop type (11), one into the duodenum just below the

pylorus and the other into the duodenum at the ligament of Treitz or into the jejunum a few centimeters caudalward. All operations were done with the animals under ether anesthesia using surgical technic.

Two weeks or more elapsed after operation before observations were made on the animals. The dogs were fasted eighteen to twenty-four hours prior to each experiment. Studies were made in the fasting state and after the ingestion of the various standard meals. The diets administered consisted of 200 gm. of ground lean meat, a mixture of 300 cc. of milk and 200 cc. of syrup, 125 gm. of lard and 75 gm. of crackers, and 200 gm. of fresh horse fat, respectively. The

dogs were found to ingest this last more readily than the other type of fat meal.

Specimens were removed by soft rubber catheters through both proximal and caudal fistulas at intervals of a half hour and the pH values were ascertained. This procedure was usually repeated on two or three different days for each diet. The pH was determined with the quinhydrone gold electrode.

After establishing these control readings, studies on the effect of injection of acid on the reaction of the duodenal content were made. The dogs were trained to lie quietly without restraint on specially arranged stands during intervals required for the observation. Five-tenths per cent hydrochloric acid was introduced continuously at a fixed rate by the gravity drip method through rubber tubing connected to a catheter in the

denal end inverted. The proximal end of the pylorus was anastomosed to the jejunum to restore the continuity of the gastro-intestinal tract. The distance from the site of the anastomosis to the opening of the caudal fistula was usually about 30 cm.

The studies which were performed before the pylorus was cut off from the duodenum were repeated on the isolated duodenum (Fig. 2).

## RESULTS

**DUODENUM INTACT.**—The reaction of the duodenal content obtained through the proximal fistulas of fast-ing dogs was usually within a range of 6.15 to 8.15, with an occasional lowering to 2.59, whereas that obtained through the caudal fistulas ranged from 6.33 to 8.22, with an extreme acidity of 4.97.

### SECOND STAGE (AFTER ISOLATION OF THE DUODENUM)

Average results on 7 healthy dogs.

Readings taken at 15 minute intervals for 2-hour periods.

#### CONTROL READINGS: DISTAL FISTULA

|                   | pH           | Extreme low readings, pH |
|-------------------|--------------|--------------------------|
| Fasting state     | 7.07 to 8.11 |                          |
| Protein meal      | 7.00 to 8.18 | 6.65                     |
| Carbohydrate meal | 7.00 to 8.01 |                          |
| Fat meal          | 7.00 to 8.01 |                          |

#### NEUTRALIZING POWER

|                   | 0.5 per cent HCl, C.C. |
|-------------------|------------------------|
| Fasting state     | 150 to 180             |
| Protein meal      | 180 to 210             |
| Carbohydrate meal | 180 to 210             |
| Fat meal          | 180 to 210             |

Fig. 2. Method of administration of solutions to the isolated duodenum. The neutralizing power indicates the volume of hydrochloric acid that may be introduced into the duodenum in two hours without changing the pH of the fluid from the distal end of the duodenum.

proximal fistula, (Fig. 1). The pH of specimens collected from the distal fistula every fifteen minutes for a two-hour period was determined. Such a procedure was repeated on separate days until a determination

of the maximal amount of acid that could be introduced into the proximal end of the duodenum without materially changing the reaction of the content of the distal portion was made. This was considered to be the capacity of the duodenum to neutralize, buffer, and dilute acid under the particular conditions that obtained.

Quantitative determinations of chloride ion were made before and after the ingestion of diets to estimate the amounts of buffered as well as unbuffered acid escaping through the pylorus with each type of meal. Similar studies were conducted before and after introduction of hydrochloric acid to approximate the portion of the latter that was actually buffered.

The second stage operation consisted of isolation of the proximal end of the duodenum (Fig. 2). To accomplish this the pylorus was sectioned and the duo-

The reaction of the content of the lower end of the duodenum for a two-hour period following the fat and carbohydrate meals did not differ materially from the fasting values. The readings after the carbohydrate

meal ranged from 6.00 to 7.83, and following ingestion of the fat diets from 6.66 to 8.01. Bizarre fluctuations practically never occurred.

More acid values obtained with the protein meal. The hydrogen ion concentration varied from 5.34 to 7.44 in most instances, with occasional low readings of 4.48.

The chloride ion level of the content of the distal end of the duodenum was lowest after fat and carbohydrate meals and highest following the meat diet. With the two animals studied in this regard a slight decrease in chloride content occurred after ingestion of horse fat. Before the meal, values of 2.60 and 1.70 mg. of chloride ion per cc. of duodenal content were obtained, whereas for two hours after the fat was eaten average figures of 2.11 and 1.58, respectively,

were noted. After the meat meal, on the other hand, an increase in the chloride level was evident. The readings before the meal were 1.45 and 1.80, with a rise to 2.79 and 2.50, respectively, afterward. Similar determinations with the carbohydrate diet yielded inconsistent results.

Fasting levels of chloride ion in the other dogs ranged from individual averages of 1.43 to 3.06 mg. per cc. of duodenal content obtained through the distal fistula.

The appearance of specimens removed varied in fasting animals. Pale secretions of the pancreatic type, light yellow samples the color of hepatic bile, and deep yellow or brown fluid considered characteristic of gallbladder bile were obtained. These were either clear and thin or cloudy and viscid and usually contained considerable mucus. Within fifteen to thirty minutes after meals the duodenal content usually assumed the color, characteristic of the particular diet, namely, dark yellow or brown after meat, light yellow (with curds) after milk and syrup, and light yellow after fat. Specimens of the last were usually of a creamy consistency and would often solidify on standing over night in a cool place. Not infrequently, however, clear samples, resembling those obtained from fasting dogs, were obtained after feedings.

The neutralizing capacity of the duodenum, as determined by the continuous introduction of acid for two-hour periods, ranged from 1 to 1.5 cc. of 0.5 per cent hydrochloric acid per minute (1440 to 2160, or an average of 1800 cc. per day) in the various fasting animals. Following the carbohydrate meal, this capacity usually did not differ materially from that with the animals in a fasting state. The capacity of the various dogs ranged from 0.75 to 1.25 cc. of 0.5 per cent hydrochloric acid per minute. The administration of the protein meal usually resulted in a lowering of the neutralizing capacity by about 0.25 cc. per minute of the 0.5 per cent acid, although in one animal no difference from the figure obtained in the fasting state was noted.

Contrary to these findings, all but one of the animals, after receiving a fat meal, showed a capacity to neutralize an average of 0.25 cc. per minute more than with the other diets. The one dog which neutralized equal amounts of acid when in a fasting state and following a fat meal received the diet of 125 gm. of lard and 75 gm. of crackers. All of the others except one were given 200 gm. of horse fat.

The chloride content of the duodenal specimens, removed from fasting animals receiving amounts of acid continuously neutralized, was materially greater than the fasting control level. The average determinations of the different animals varied from 2.60 to 2.87 mg. per cc. of duodenal content.

**DUODENUM ISOLATED.**—The pH of the duodenal content obtained from each fistula remained within limits of 7.00 to 8.25 regardless of diet or state of alimentation with the exception of one animal in which an extreme distal fistula reading of 6.59 occurred.

Individual chloride averages of 1.13 to 2.37 mg. per cc. of duodenal content obtained.

In fasting animals it was usually not possible to secure specimens in quantities of more than 1 to 2 cc.

Indeed, at times, no sample could be removed. The fluid obtained was usually pale, or light to dark yellow, and was either thin or of mucous consistency. On the other hand, within three to five minutes or more after food of any type entered the stomach, amounts of from 3 to 6 cc. of duodenal contents could invariably be obtained. These specimens were usually relatively clear and the color had no consistent relationship to the type of meal ingested. Reflux of stomach content from the jejunal loop was an unusual occurrence. In fact this was noted on an average of but once in approximately fifteen specimens taken at half hour intervals. After permitting the dogs merely to smell meat, increases of only 1 to 2 cc. in the available quantity of duodenal secretions was noted.

The neutralizing capacity of the isolated duodenum of fasting animals was 1.5 to 1.75 cc. of 0.5 per cent hydrochloric acid per minute (2160 to 2520, or an average of 2340 cc. per day) for two-hour periods. This was equivalent to, or but slightly in excess of, the capacity of the intact duodenum during the same intervals following a meal of horse fat but was 0.25 to 0.5 cc. per minute (360 to 720, or an average of 540 cc. per day) more than when other conditions obtained in the dogs prior to isolation of the duodenum. The neutralizing capacity for similar durations following all diets was usually 0.25 cc. per minute greater than that of the fasting dogs. The average chloride content of specimens collected during the administration of acid was elevated to levels of 2.34 to 3.8 mg. per cc.

The two-hour neutralizing capacity in the fasting state of 1.75 cc. of 0.5 per cent hydrochloric acid per minute of two dogs was found to be maintained for twenty-four hours. Samples collected at half-hour intervals were neutralized with but few exceptions. From the observations on one of the animals, which received 200 gm. of lean meat every four hours, it appeared that the slight increase in neutralizing power of the isolated duodenum following meals subsided within two to three hours. After the first meat meal, subsequent four-hour feedings produced no evident change in neutralizing capacity.

Following the introduction of 0.15 per cent hydrochloric acid, continuously for two-hour periods, it was found that the same number of grams of hydrochloric acid was neutralized as with the introduction of 0.5 per cent acid.

Samples collected after the introduction of single amounts (10 to 100 cc.) of fifth to twentieth normal acid showed complete neutralization, no elevation of the chloride level, and absence of free hydrochloric acid in four to ten minutes. An increase in duodenal content was noted for an hour after the introduction of acid.

## RESULTS OF STUDIES PERFORMED IN VITRO

In vitro, approximately three parts of duodenal content obtained ten minutes after the introduction of acid ceased neutralized 1 part of 0.5 per cent hydrochloric acid. Specimens (6 cc. obtained from two dogs on which only second stage studies were made), having reactions of pH 7.51 and 7.68, mixed with 2 cc. of 0.5 per cent acid had resultant hydrogen ion concentration of 6.83, and 7.07, respectively.

The addition of equal parts of duodenal content with a pH of 5.64 to the fat, protein and carbohydrate

meals brought about the respective reactions: 6.63, 6.00, and 6.00.

### COMMENT

A possible source of error in this study is the occasional reflux of gastric content through the jejunal loop into the duodenum. This could not be completely excluded; however, as has been previously stated, it occurred so infrequently (once in fifteen readings) that it cannot be considered an important error. Complete isolation of the duodenum obviously would have prevented this source of error, but, as Walters and Bollman, Gamble and McIver (4), and others have pointed out, the resulting loss of duodenal secretions, especially that of the pancreas, is incompatible with prolonged life of the animal. On the other hand, the operative procedures used in this study, although not truly physiologic, were found to be consistent with maintenance of a well nourished and apparently healthy state in the dogs used. It seems, therefore, that from such a standpoint the results of this investigation may be deemed reasonably valid.

Although transient acid reactions occurred at the caudal end of the intact duodenum of fasting animals, these fluctuations were more marked in the upper portion, namely the ulcer-forming region. Such a finding fits in with the conception of acidity being a factor in the occurrence of peptic ulcers in this region. The more acid readings following meat meals appear referable to an increased secretion of hydrochloric acid in the stomach in excess of the buffering capacity of protein. The appreciable increase in chlorides of the duodenal content after these meals substantiates such a deduction.

The same reasoning applies conversely to the more uniform alkalinity occurring after fat meals. The low chloride levels of the fatty specimens of duodenal content obtained following this type of diet indicates a minimal secretion of acid in the stomach. This finding is in accord with the current conception of the effect of a fat diet on gastric secretion. Hebert, working in this laboratory, found negligible amounts of free hydrochloric acid in the stomach of dogs with gastric fistulas two hours after ingestion of the horse fat meal used in this study. Vanzant noted that feeding ulcer patients oil in the evening prevented the characteristic nocturnal rise of acidity. Graham and Emery, Kosaka, Lim, Ling and Liu report inhibition of the secretion of gastric acid by fat.

It seems reasonable to assume that the somewhat greater neutralizing power of the duodenum with fat meals and the slight decrease in this function following meat diets is likewise attributable to lesser and greater amounts, respectively, of acid that could be introduced through the upper fistula without changing the reaction at the lower end of the duodenum. Furthermore, such results were not found after isolation of the duodenum.

The part played by the buffering qualities of the various diets used in this study is problematical. The uniform reaction of the isolated duodenum supports the belief that the transient acid fluctuations occurring in the intact duodenum are the result of spurts of gastric content passing through the pylorus.

The somewhat higher neutralizing capacity that occurs for a short time after meals in the isolated duodenum seems to be essentially the result of an augmented flow of the secretions poured into the

duodenum incident to the presence of food in the stomach. It is possible that gastric chyme coming in contact with the jejunal mucosa at the site of a gastrojejunal stoma would liberate sufficient secretin to produce this effect. Winton and Bayliss stated that the pancreas responds to reflex vagus stimulation. They remarked that the pancreatic secretion occurring a few minutes after taking food, before any chyme could reach the duodenum, is abolished by cutting the vagus nerves. These workers believed that such a secretion results from psychic stimulation. Puestow observed a "psychic" secretion of bile, lasting one to three minutes, and an increased flow of bile was noted in the isolated segments of the duodenum of dogs for three to four hours after meals. The dogs used in the present investigation, however, showed but little increase in duodenal secretion after seeing and smelling food. It appears that the duodenum responds similarly to strengths of acid in the range of 0.15 per cent to 0.5 per cent, since an equal number of grams of hydrochloric acid introduced in these dilutions was neutralized, buffered, and diluted.

The question of whether acid is absorbed in the duodenum seems clarified in some measure by the chloride determinations. In view of the material increases in the chloride level of the duodenal content following the continuous introduction of acid in relatively small amounts, it appears that most of the acid is buffered and that the absorption of hydrochloric acid, as such, in the duodenum is negligible, although it must be recognized that the chloride content of the three secretions found in the duodenum may be a source of error.

A 0.5 per cent hydrochloric acid solution could be injected into the proximal end of the intact duodenum at a rate varying from 1 to 1.5 cc. per minute for a two-hour interval without altering the reactions of the duodenal content obtained from the distal end of the duodenum. If it is assumed that the injection could be maintained for a twenty-four hour period at the same rate, the duodenum could maintain a normal reaction of its content as expelled into the jejunum after receiving 1800 cc. of 0.5 per cent acid per day. The capacity of the isolated duodenum was 1.5 to 1.75 cc. of 0.5 per cent hydrochloric acid per minute, or an average of 2340 cc. for a twenty-four hour period. According to Dragstedt and Ellis, the isolated stomach of the dog will secrete an average of 1800 cc. of 0.45 to 0.5 per cent hydrochloric acid per day. From these figures it would appear that although a considerable amount of acid reaches the duodenum in the gastric content, a larger amount of the acid produced in the stomach is neutralized, buffered, and diluted before it is expelled into the duodenum.

The determination that the duodenum before isolation is capable of neutralizing an average of 1800 cc. of 0.5 per cent hydrochloric acid in twenty-four hours, in addition to the acid passing through the pylorus, suggests that the duodenum, like the liver, kidney, and other viscera, has a reserve function in this respect considerably in excess of physiologic needs.

### SUMMARY AND CONCLUSIONS

An effort was made in this study to ascertain the actual capacity of the duodenum to neutralize, buffer, and dilute acid. Fistulous openings were made at each end of the duodenum in dogs. Control hydrogen ion determinations of the duodenal content obtained

through the fistulas were made. Acid of a strength within physiologic limits was introduced through the proximal fistula and the reaction of specimens of duodenal content removed through the distal fistula was determined. The chloride level of the duodenal content before and after standard meals and the introduction of acid was likewise estimated. The duodenum was subsequently isolated to prevent influx of gastric content and similar studies were performed.

From the results obtained certain deductions seem justified: 1. Before isolation, an apparent slight increase in the neutralizing capacity of the duodenum following ingestion of a fat meal, and the usual decrease noted after a protein meal, seem attributable

to inhibition and stimulation, respectively, of gastric secretion. 2. A transient increase in neutralizing capacity of the isolated duodenum following meals seems to be the result of an augmented flow of the secretions poured into the duodenum incident to the presence of food in the stomach. 3. It appears that acid introduced continuously in relatively small amounts is largely neutralized, buffered, and diluted, and that the absorption of hydrochloric acid, as such, in the duodenum is negligible. 4. Acid introduced in large single injections is quickly swept through the duodenum by peristalsis. 5. The duodenum has a reserve function to neutralize acid materially in excess of physiologic needs.

## The Reaction of the Duodenal Content After Exclusion of Bile from the Duodenum\*

By

JERRY W. McROBERTS, M.D.\*\*  
ROCHESTER, MINNESOTA

IT was the purpose of this investigation to determine the effect of loss of bile on the reaction of the duodenal content. The ranges in reaction of the duodenal content of normal dogs during fasting and after the ingestion of various test meals were obtained. A biliary fistula was then made and the observations were repeated.

### METHODS OF EXPERIMENTATION

The necessary duodenal fistula, using the transposed intestinal loop method (2), was made in each animal and the usual postoperative care was instituted. All operations were done with animals under ether anesthesia and using surgical technic. The first series of

observations were made about two weeks after operation for duodenal fistula. The animals were fasted for twenty-four hours before each test. A specimen of the duodenal content of the fasting animal was obtained. One of the following four standard test meals was then given: 100 gm. of lean horse meat, 200 gm. of lean horse meat, 100 gm. of lard mixed with 100 gm. of cracker meal, and 100 gm. of syrup mixed with 500 cc. of milk. Specimens of duodenal content were removed and the pH determined every half hour following the ingestion of the test meal for a period of seven hours. Observations were made three times with each of the test meals. The hydrogen ion concentration of the duodenal content was determined with the quinhydrone gold electrode.

When the variation in pH of the duodenal content following each meal was established for each animal, a biliary fistula was made using the method devised by

\*Abstract of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Surgery.

Submitted, May 12, 1935.

Rous and McMaster. Four or five days after making this biliary fistula a second series of observations was begun and the reactions of the duodenal content during fasting and after the ingestion of the test meals were determined.

## RESULTS

*Normal reaction of the duodenal content.*—The ranges in pH of the duodenal content of normal animals were in general similar to those reported by Mann and Bollman (3) and in the preceding paper (1). The reaction of the specimen of duodenal content obtained after twenty-four hours of fasting was usually slightly alkaline. In eighty fasting specimens, the extreme readings were pH 4.68 and pH 7.83. The reaction of the specimens obtained from three dogs every half-hour from twenty-four to thirty-one hours of fasting indicated a narrow range of variation about the neutral point, pH 7.00.

There was one outstanding feature of the reactions of duodenal specimens obtained after the feeding of the test meals and that was the wide range in fluctuation in the determinations of pH that frequently occurred in successive specimens. This has been noted by Mann and Bollman (3). It was not unusual for the reaction to vary from about 7.00 to about 3.00 in specimens withdrawn after an interval of a half hour. When such a low reading occurred after several high readings, it was not unusual for the pH of the next specimen to return to the previous high level. These results make it difficult to plot typical curves of the reactions of the specimens obtained after feeding. The most that can be said is that the determinations after a specific test meal resembled one another in the range of their variations.

The reactions of the specimens removed half an hour following a meal of 100 gm. of lean horse meat were usually acid whereas those an hour after feeding were invariably so. Specimens obtained one to four and a half hours after feeding were most acid and the reactions were usually between pH 5.00 and 3.00. After the four and a half hour period, the readings became less acid and, at the end of seven hours, were frequently neutral. However, it was not unusual for the readings to remain as acid as pH 5.00 seven hours after feeding meat.

The reactions of the specimens obtained after 200 gm. of lean horse meat varied but little from those obtained after 100 gm. of meat for the period of four and a half hours after feeding. From the four and a half to the seven-hour period the reactions after 200 gm. of meat usually remained as acid as before.

The specimens removed half an hour after the feeding of 100 gm. of corn syrup with 400 cc. of milk usually contained fine particles of curd. The acidity of the specimens generally varied between about pH 5.00 and 7.00 although occasionally more acid readings, as low as pH 4.00, occurred. The readings did not show such rapid fluctuations in acidity as those following a

meal of meat. At the end of seven hours, the reactions of the specimens were usually about neutral.

The majority of the specimens withdrawn after a meal of 100 gm. of lard with 100 gm. of cracker meal varied in acidity between the narrow range of pH 6.00 to 7.00. Two or three of the specimens within the seven-hour period usually showed a comparatively high acidity, which often reached pH 3.00. Generally, the following specimen would be between pH 6.00 and 7.00, although occasionally the acidity would fall more gradually.

*Results after making biliary fistulas.*—Three or four days after the operation for biliary fistula the second series of observations was begun. These observations were conducted under the identical conditions that prevailed during the first series. All the animals lost from 1 to 2 kg. during the first week after this second operation; but, after this initial loss, they usually maintained their weight. All of the animals readily ate the meat meals. Some of them showed a disinclination to eat the meal of milk and syrup, but all could be induced to do so. There was a tendency for them to refuse the meal of fat.

The reaction of specimens removed from dogs fasting from twenty-four to thirty-one hours after biliary fistulas had been made varied within the same range as specimens from normal dogs during the same period of fasting. The reactions of the specimens withdrawn twenty-four hours after feeding and just preceding the administration of the test meal were frequently slightly more acid than those obtained under normal conditions.

After the two meat meals, the reactions of the specimens compared very closely with the normal. The rise in acidity during the first four and a half hours and the subsequent return to about neutral was duplicated after 100 gm. of meat. After 200 gm. of meat, the acidity increased and remained about the same level as occurred in the experiments under normal conditions.

The loss of bile from the intestine did not cause any difference in the reactions of the specimens withdrawn after a meal of milk and syrup when compared with those obtained under normal conditions. In both series there was a variation in the specimens between pH 4.00 and 7.00.

The duodenal specimens following a meal of lard and crackers were generally more acid than normal specimens; whereas the reactions of the normal specimens varied between pH 6.00 and 7.00, these specimens usually ranged between pH 2.00 and 5.00.

## SUMMARY

Observations were made on the changes in pH of the duodenal content of dogs following various diets before and after draining the bile to the outside of the body. The results indicate that the loss of bile did not significantly alter the pH of the duodenal content under the conditions of these experiments.

# The Effect of Exclusion of the Pancreatic Secretion by Evulsion of the Pancreatic Ducts on the Reaction of the Duodenal Content\*

By

M. TISCHER HOERNER, M.D.\*\*  
ROCHESTER, MINNESOTA

THE secretion of the pancreas has usually been considered the most important of the three major secretions draining into the duodenum in maintaining the normal reaction of the duodenal content. It was the purpose of this investigation to attempt to quantify this important function of the pancreas.

The early literature on the subject can be briefly summarized by the statement that the results were quite variable, often contradictory, and possibly also unreliable. Uniformity of results was not obtained because of errors due to the disturbed function of the gastro-intestinal tract which were necessarily produced in the securing of specimens of duodenal content. The source of these errors was in the main corrected by the development of a satisfactory method of making a duodenal fistula.

## METHOD

Duodenal fistula, of the transposed loop of intestine type, was made in each animal used in this investigation. All operations were done with animals under ether anesthesia and using surgical technic. The routine procedure in making observations was as follows: The dogs were fasted for twenty-four hours before each test. After securing a specimen of duodenal content in the fasting state, the animal was fed one of the standard test meals. These test meals, four in number and representing a meal of protein, carbohydrate, and fat, were composed of the following foods: (1) 100 gm. of lean horse meat, (2) 200 gm. of lean horse meat, (3) 100 gm. of syrup mixed with 500 cc. of skimmed milk, and (4) 100 gm. of lard mixed with 100 gm. of cracker meal. Specimens of duodenal content were taken from the duodenal fistula at intervals of a half hour for eight hours or longer. For control observations the reaction of the duodenal content was determined in the same manner by omitting the test meals. The hydrogen ion concentration was determined by the quinhydrone gold electrode. Observations were repeated using the various diets until representative figures were secured for each animal.

As the next step in the investigation, the pancreatic ducts were evulsed. It is common knowledge that simple ligation of the pancreatic ducts does not obstruct the flow of pancreatic secretion, except for a very short period, as the ligature soon cuts through the duct establishing its patency. In order to obviate this chance for failure the ducts were evulsed by the following technic: Each duct was exposed at its point of entrance into the duodenal wall. A small hemostat

was placed securely on each duct and the duct was sectioned between the clamp and the duodenal wall. The clamp was then rotated, winding the duct around its lower end. In this manner all the ductal system was removed from the gland except the smaller tributaries. The procedure has been found to be perfectly safe as regards the life of the animal, and patency of the ductal system has never been established after the ducts were evulsed satisfactorily in this manner. The entire series of observations previously described were repeated on each animal after evulsion of the pancreatic ducts.

## RESULTS

It may not be entirely correct to consider that specimens withdrawn from a duodenal fistula are obtained under normal physiologic conditions, but since the animals remained in such excellent health and no change in gastro-intestinal function was demonstrable, such an assumption seemed justifiable in this research. It was found to be practically impossible to obtain a typical curve for the acidity of the duodenum during fasting and following the various types of diets used in the experiment, owing to continual variation of the reaction at all times. The wide range of fluctuation in successive specimens was remarkable. It was not unusual for samples taken at half-hour intervals to vary from a pH of 7.20 to 3.60. Thus the graphs made from these determinations consisted of a series of graduated spikes. The most that could be said of the results following a specific test meal was that they resembled each other in their range of variation.

*Normal reaction of the duodenal content.*—The reaction of the duodenal content during fasting was usually alkaline, varying from pH 7.00 to 7.81. However, if a sample was taken soon after the pylorus of the stomach had admitted a quantity of acid material, a pH as low as 3.31 was detected. Readings of 6.60 were not infrequent.

After a meal of 100 gm. of meat, the reaction of the duodenal content one-half hour later usually varied from pH 6.75 to 4.99, but determinations as low as 3.78 were observed. During the next one or two hours the fluctuations were marked, ranging from pH 6.40 to 3.50 with some readings as low as 1.93. Subsequently there was a gradual rise in the pH toward neutrality, but at any period during the next five hours a determination as low as 4.30 might be obtained. A value characteristic of the fasting state was never observed before six and a half hours, and at times not before ten to twelve hours, after the ingestion of food. Although a typical curve could not be obtained because of the irregular, marked fluctuations, it was noted that after the rapid decrease of the pH during the first two or

\*Portion of abstract of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Ph. D. in Surgery.

\*\*Fellow in Surgery, The Mayo Foundation, Rochester, Minnesota. Submitted, May 12, 1935.

Fig. 1

three hours, there was a gradual tendency toward neutrality.

Following a meal of milk and syrup, the reaction of the duodenal content changed very little during the first half hour and was usually observed between pH 6.98 and 6.25. For the next two hours fluctuations as low as 4.26 were noted, but most of the values were not as low as those obtained with a meat diet. After the first two or three hours the return toward neutrality was rapid, but frequently, about six hours after the taking of the meal, there was a mild secondary decrease in the pH. Nevertheless, fasting readings were usually obtained from seven to eight hours after the ingestion of food.

A fat meal lowered the acidity of the duodenal content only to a slight extent, and the reaction remained fairly constant. The pH rarely decreased below 5.20 in the first two or three hours after taking food and thereafter usually varied from 6.80 to 6.25 with occasional readings of 5.80. However, at some period during the day a reading as low as 4.21 might be observed.

*Reaction of the duodenal content after evulsion of the pancreatic ducts.*—Following evulsion of the pancreatic ducts, the animals progressively lost weight although their appetite was excellent and they ate all the food offered them. When observations were not being made, the animals were fed the whole pancreas of calves three times a week with their regular rations. Their stools became exceedingly large, frequent, fatty, and rancid in odor. However, the animals remained very active and were apparently in excellent health except for the loss of weight.

During fasting, the range of variation in the reaction of the duodenal content was the same after evulsion of the pancreatic ducts as before, although wide fluctuations were more frequent than in the normal dog (Fig. 1).

Fig. 1. Variation in pH of the duodenal content of the fasting dog before and after evulsion of the pancreatic ducts.

Following a protein meal, the acidity of the duodenal content was increased more rapidly and was maintained for a longer period than before pancreatic secretion was eliminated. This result suggested the possibility that, owing to the absence of the pancreatic juice, the total buffer substances present were insufficient to maintain a normal reaction when a large quantity of highly acid chyme was poured into the duodenum. However, when the chyme decreased in amount, the quantity of available alkali was capable of gradually returning the reaction to normal (Fig. 2).

After a carbohydrate meal, the reaction of the duodenal content in a few instances closely approximated the average of the determinations obtained for the normal animal. However, in the majority of observations the increase in acidity came earlier after the ingestion of the meal, although it was not so soon or so great as occurred after taking meat, and was maintained for a longer period of time than in the normal dog (Fig. 3). The difference between the reaction of the duodenal content following a meat and a carbohydrate meal might have been the result of the fact that the carbohydrates were less stimulating than meat to acid secretion in the stomach, and thus the bile and succus entericus, although weaker buffering agents and not markedly stimulated by the carbohydrates, were able to maintain a more normal reaction.

As in the normal dog, a fat meal was followed by only a slight lowering of the acidity of the duodenal content. It is usually considered that fat is a depressant to gastric secretion. Thus it was reasonable to assume that, following a fat meal, the absence of the pancreatic juice had no effect on the reaction of the duodenal content because of the relatively low acidity of the chyme leaving the stomach.

Observations were continued for a period of two months following evulsion of the pancreatic ducts. All the animals were very active and apparently in the best of health at the end of this time except for loss in weight. Although the pancreas on examination at

Fig. 2

Fig. 2. Variation in pH of the duodenal content of a dog after a protein meal before and after evulsion of the pancreatic ducts.

Fig. 3

necropsy was found to be merely a thin fibrous cord, no evidence of diabetes was discovered at any time during the investigation, which observation is in agreement with previous investigations.

#### COMMENT

Several sources of error which had to be eliminated were encountered in the course of the investigation. Owing to the innumerable conditions affecting the normal physiologic action of the gastro-intestinal tract, the training of the experimental animals was found to be an important factor. It was also noted that adherence to a regular routine was necessary in order to obtain consistent and reliable results. Although collection of the specimens was a simple process, care had to be taken that the catheter was not inserted too far. The position of the catheter in the duodenum was carefully checked by noting the length of the fistula at operation, marking the catheter, taking roentgenograms, and by fluoroscopic examination. As previously stated, it was necessary to evulse completely both pancreatic ducts and also to search carefully for an accessory duct that might have been overlooked. In one dog the minor duct broke before it was evulsed completely. On exploration three weeks later this duct was found to be patent and that portion of the pancreas which it drained was of normal size and appearance. The duct was again evulsed and the determinations repeated. Because of this observation in one case, the remainder of the dogs used in the investigation were explored and found to have small, fibrotic, atrophic pancreases.

Some of the results of this investigation necessitate additional comment. As might be expected, marked fluctuations in the acidity of the duodenal content of the normal animal were noted following administration of various types of test meal. On some days the observations were fairly consistent, but on others the fluctuations were remarkably varied. The same could be said of the results obtained following evulsion of the pancreatic ducts. These irregular determinations are explained by the fact that the reaction of the duodenal content is dependent on the saliva, food, gastric juice, bile, succus entericus, and pancreatic juice, and the rate at which the gastric content passes into the

Fig. 3. Variation in pH of the duodenal content of a dog following a carbohydrate meal before and after evulsion of the pancreatic ducts.

duodenum, all of which are exceedingly variable factors. Additional emphasis should be placed on the fact that the reaction of the duodenal content was always so varied that an average of the pH at any period was not a reliable index of the reaction at that time. Graphs made from the most characteristic figures obtained from each dog were the best means of illustration. In this investigation the absence of pancreatic juice produced a moderate change in the reaction of the duodenal content during fasting and following the protein and carbohydrate meals. In the first instance the change was characterized by more frequent low fluctuations, which were possibly due to the failure of the content of the fasting stomach to stimulate sufficient buffer substances because of the diminished amount immediately available. The variations in the duodenal content were more significant and consistent following meals of protein and carbohydrate, for the acidity was rapidly increased and was maintained at a higher level for a longer interval before returning toward neutral. Probably these results could not be accounted for by changes in the hydrogen ion concentration of the alkaline secretions alone, for undoubtedly dilution was an important factor. Thus the diminished amount of total buffers available could not cope with the large quantity of highly acid chyme. However, when the chyme decreased in amount and acidity, the reaction was gradually returned to normal. Perhaps such an assumption is controversial, but the fact remains that the bile and succus entericus, while usually of minor importance in the reaction of the duodenum, apparently are capable of maintaining the reaction of the duodenal content almost normal in the absence of pancreatic secretion.

#### SUMMARY

Determinations of the reaction of the duodenal content of dogs were made before and after evulsion of the pancreatic ducts in the fasting state and after the ingestion of various standard test meals. The reaction of the duodenal content in the fasting state was usually alkaline, ranging from pH 7.00 to 7.81. After a meat meal, the pH varied between 6.40 and 3.50. Following a carbohydrate meal, the reaction ranged from 6.75 to 4.26. The fat meal caused fluctuations from 6.80 to 5.20. Thus the acidity of the duodenum after meals appeared to depend largely on the rate and amount of acid formation in the stomach.

Following evulsion of the pancreatic ducts, the reaction of the duodenal content during fasting possessed the same range of variation as when the pancreatic secretion was present, but determinations on the acid side of neutrality were obtained more frequently. Both protein and carbohydrate test meals caused the duodenal content to become acid in reaction more rapidly, and the reaction was maintained for a longer period before returning toward neutrality after loss of the pancreatic secretion than in the normal state. With the pancreatic juice absent, the total buffer secretions in the duodenum were diminished, but the remaining secretions, bile and succus entericus, were capable of maintaining a normal reaction of the duodenal content except when a gastric content of high acidity entered the duodenum.

# The Effect of Exclusion of the Pancreatic Secretion by a Pancreatic Fistula on the Reaction of the Gastric, Duodenal and Jejunal Contents\*

By

M. TISCHER HOERNER, M.D.  
ROCHESTER, MINNESOTA

THE effect of the loss of the secretion of a gland is not necessarily the same as the effect of preventing the gland from secreting. The secretion of the pancreas is a pertinent example. The loss of pancreatic secretion produces a rapidly fatal result unless appropriate treatment is instituted. On the other hand, evulsion of the pancreatic ducts, preventing the production of pancreatic secretion, produces no untoward effects except those associated with the resulting decrease in intestinal digestion. The results of eliminating the pancreatic juice, by preventing the pancreas from secreting, on the reaction of the duodenal content were presented in the previous paper. It was the purpose of this investigation to determine what changes in the reaction of the content of the upper portion of the gastro-intestinal tract occur when the pancreatic secretion is eliminated by draining it to the outside of the body.

## METHOD

Gastric, duodenal, and jejunal fistulas, as well as combinations of these fistulas, employing the transposed loop of intestine method, were made (3) and utilized in obtaining specimens of the content of the upper portion of the gastro-intestinal tract at half-hour intervals for an eight-hour period. The hydrogen ion concentration of this material was determined at once with quinhydrone gold electrode. Samples of the content of the various portions of the gastro-intestinal tract were collected during fasting and following the administration of the standard protein, carbohydrate, and fat test meals until representative figures were secured for each animal. Having obtained the necessary preliminary data, pancreatic fistulas were made using a technic similar to that of Elman and McCaughan. It was found advantageous to feed the dogs 50 gm. of meat about three hours before the operation. Thus the major pancreatic duct was more easily cannulated and secretion immediately began to flow through the tube, preventing the formation of blood clots that might lead to obstruction of the cannula. The same series of tests were then performed and similar observations instituted the day following operation. The animals were given daily 300 to 600 cc. of physiologic saline solution intravenously, depending on the size of the animal and the amount of pancreatic juice secreted during the preceding twenty-four hours. This procedure, so necessary for the maintenance of life, replaced both the fluid and salt which had been lost from the pancreatic fistula and by vomiting. The operations

were performed with animals under ether anesthesia and employing sterile technic.

## RESULTS

Elman and McCaughan reported that death invariably resulted in from five to eight days when the entire external pancreatic secretion of dogs was excluded from the intestine by drainage to the outside of the body. However, the later work of McCaughan revealed that, if the whole pancreatic juice was returned to the dog by mouth or large quantities of physiologic saline solution were injected intravenously daily, no untoward effects were noted. The results of these experiments substantiated the findings of the foregoing authors. Although the dogs in this group ate fairly well, they gradually lost weight, and practically all of them developed a tendency to vomit occasionally. As in the case of evulsion of the pancreatic ducts, the stools became large, fatty, and rancid in odor.

*Effect on the reaction of the gastric content.*—The reaction of the gastric content (after establishing the pancreatic fistula) during fasting and following the ingestion of the standard test meals was always within normal limits.

*Effect on the reaction of the duodenal content.*—Specimens of the duodenal content during fasting usually had a pH between 7.00 and 7.78, but variations from 6.80 to 5.41 were sometimes observed. Nevertheless, when samples were taken at half-hour intervals for an eight-hour period, an occasional acidity as low as 3.07 was detected among these alkaline and slightly acid readings. A comparison between these findings and those from the normal dog revealed that, following the production of a pancreatic fistula, determinations below pH 7.00 were more frequently obtained and the levels reached were somewhat lower in the majority of cases.

The reaction of the duodenal content the first half-hour after a meat meal was found to be between pH 5.95 and 4.12, but during the next two or three hours it ranged from 4.50 to 2.50. Although there was then a tendency to return toward neutral, the majority of the subsequent determinations remained between 5.00 and 3.98. When the pancreatic secretion was eliminated by draining to the outside of the body, the results were similar to those obtained when the gland was prevented from secreting (Fig. 1).

One-half hour after the administration of a test meal composed of milk, syrup, and water, the pH of the duodenal content ranged from 6.60 to 5.88. A further increase in the acidity, fluctuating between 5.95 and 4.20, was detected during the following two or three hours, but a specimen with a pH as low as 3.69 was occasionally collected. Thereafter, although

\*Portion of abstract of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Ph. D. in Surgery.  
Fellow in Surgery, The Mayo Foundation.  
Submitted May 12, 1935.

Fig. 1

the reaction usually returned to a higher level, varying between 6.50 and 5.06, a reading of 4.21 was sometimes obtained, which not infrequently was the lowest determination occurring throughout the day (Fig. 2).

After a fat meal, no deviation from normal could be detected in the pH of the duodenal content following the production of a pancreatic fistula.

*Effect on the jejunal content.*—By the time the gastric content admitted into the duodenum had reached the jejunum, its reaction was neutral or was slightly alkaline. The loss of pancreatic secretion did not appear to injure the mechanism accomplishing this change except when a protein test meal had been administered.

The ingestion of a protein meal was followed by a gradual decrease in the pH of the jejunal content until a level of 5.00 was reached about two and a half hours after the ingestion of food. Subsequent determinations closely approximated those of the normal dog, but acid readings as low as 5.78 were more frequently obtained. Thus the absence of the pancreatic juice did have a slight but appreciable effect on the reaction of the intestinal content below the duodenum with this diet.

*Comparison of results obtained with pancreatic fistulas and evulsion of pancreatic ducts.*—By careful selection of observations from each group the change in the reaction of the duodenal content could be made to appear more marked following either evulsion of the ducts or establishment of a pancreatic fistula. A reliable opinion concerning any real difference could only be formed when both series of dogs were considered in their entirety. It was then discovered that a few more acid determinations were obtained with a pancreatic fistula following protein and carbohydrate diets than after evulsion of the pancreatic ducts. However, the distinction was so slight that it should not be emphasized.

Fig. 1. Variation in the pH of the duodenal content following a protein meal before and after the establishment of a pancreatic fistula.

### COMMENT

With the aid of daily intravenous injections of physiologic saline solution the dogs remained active and in apparently good health for many days although they continued to lose weight. One animal was kept in excellent condition for thirty-four days, but there was some evidence of leakage of the pancreatic juice into the intestine about the twentieth postoperative day, and this was verified on postmortem examination. Two dogs died after continuous secretion for seven and twenty-five days, respectively, and necropsy revealed no cause of death other than the pancreatic fistulas. The findings at necropsy of two other animals, both lost on the tenth day, revealed acute perforated peptic ulcers.

It was essential to maintain a continuous flow of secretion after establishing a pancreatic fistula. The development of leakage or infection had to be detected immediately and the dogs eliminated from the series. Owing to the extreme facility with which the pancreatic juice became infected in spite of a strict aseptic technic, the remainder of the dogs, although in fairly good condition and excreting pancreatic juice freely, were sacrificed from twelve to twenty-four days postoperatively because of the presence of bacteria in the pancreatic secretion. At times the material collected from the fistula was perfectly clear and was of normal appearance, and the existence of an early infection could be detected only by special technic.

### SUMMARY

Specimens were obtained of gastric, duodenal and jejunal contents under normal physiologic conditions and their reactions were determined in the fasting state and after various test meals, before and after draining the pancreatic secretion to the outside of the body. The production of a pancreatic fistula caused no change in the reaction of the gastric content during fasting or after the various types of test meal used in the research. However, differences in the reaction

Fig. 2

Fig. 2. Variation in the pH of the duodenal content following a carbohydrate meal before and after the establishment of a pancreatic fistula.

of the duodenal content were observed after establishing a pancreatic fistula. Although the range of variation during fasting was quite within normal limits in the two conditions, low determinations were more frequently obtained for the animal with a pancreatic fistula. Protein and carbohydrate meals caused a more rapid decrease of the pH, and the reaction was usually maintained at a decreased level for a longer period before returning toward neutrality than was found be-

fore elimination of the pancreatic secretion. These same changes were also observed to a lesser degree with the jejunal content, but only after a protein diet. A comparison of the results following the production of a pancreatic fistula and evulsion of the pancreatic ducts revealed a few more acid determinations in the former after protein and carbohydrate diets. The distinction, however, was slight and should not be emphasized.

## The Buffer Capacity of the Pancreatic Juice\*

By

M. TISCHER HOERNER, M.D.\*\*

ROCHESTER, MINNESOTA

WHILE ascertaining the reaction of the intestinal content at various levels of the intestinal tract following elimination of the pancreatic secretion from the duodenum by means of a pancreatic fistula, it seemed desirable to determine whether the results obtained in previous studies could mainly be due to the absence of the secretion from the pancreas.

Bayliss and Starling stated that the alkalinity of pancreatic juice gradually fell as secretion continued. Anrep, Lush, and Palmer believed this was partly due to removal of available alkalis from the blood supply and partly to the slightly acid solutions of secretin which were used to stimulate the pancreas. Johnston and Ball noted that the pH of pancreatic juice varied from 7.16 to 8.04 during constant drainage of the secretion, and that a decrease of chloride ions was associated with an increase of bicarbonate. Ball (2, 3), also reported that the more rapidly the juice was secreted the higher its pH value, and that the bound carbon dioxide concentration of chloride and bicarbonate varied inversely. Gamble and McIver discovered that this decrease in chloride in the pancreatic juice was associated with a diminution in the chloride concentration of the blood.

Mellanby stated that secretin controlled only the alkaline fluid of the pancreatic juice, whereas the enzymes were produced by a nervous mechanism. This was in accordance with the views of Zucker, Newburger, and Berg. Dubois and Polonovski also supported this theory, for they observed that the reaction of the pancreatic secretion following the injection of secretin into five dogs varied between pH 8.4 and 8.6, and that following the injection of pilocarpine it varied between 7.8 and 8.2. Popow and Kudrjawzew found

the hydrogen ion concentration of pancreatic secretion to be inversely proportional to that of fluid introduced into the duodenum to stimulate the secretion of the juice. The work of Carnot and Gruzewska appeared to substantiate this observation, as they noted that the pancreatic secretion had a pH of 8.72 and, after injection of histamine, a pH of 8.90. In addition, Czubalski reported that the pH of the pancreatic secretion fluctuated between 7.06 and 8.64, and that the secretion was more alkaline following a protein meal (pH 8.23 to 8.64) than after the ingestion of milk (pH 7.06 to 8.45). He reasoned that since milk did not produce so high an acidity in the stomach, pancreatic secretion which had a reaction nearer neutral was produced. However, Jones felt that there was a compensatory reaction between the bile and pancreatic juice so that when the buffer action of one decreased the other tended to increase.

Under the conditions of their investigation, Elman and McCaughan found the buffering capacity of the pancreatic secretion to be very great, for 1 c.c. of the secretion would neutralize an equal amount of tenth-normal hydrochloric acid, and thus they considered it an important factor in the neutralization of acid chyme.

#### METHOD

In this experiment, 1 c.c. of the secretion secured from the pancreatic fistula was titrated with 1 c.c. of tenth-normal hydrochloric acid, a drop at a time, and the change in pH with each minute addition was determined. Samples of pancreatic juice were collected at half-hour intervals during fasting and after the ingestion of the various standard test meals and the fluctuation in the buffering capacity during the eight-hour period of observation was determined.

#### RESULTS

The pancreatic secretion was usually thin, watery, opalescent, and tasteless when flowing freely, but was somewhat more viscid and ropy in character after

Fig. 1

prolonged fasting. Protein seemed to stimulate a more copious secretion than any of the other test meals used. During fasting the amount collected was greatly diminished, but even in the fasting state the secretion was continuous, provided there was no leakage or infection. Infection of the fistulous tract did not immediately change the appearance of the pancreatic juice, but after the infection had persisted for a short time the secretion became turbid and contained small flakes, composed of bacteria, leukocytes, and bits of tissue. The amount of secretion collected was exceedingly variable, depending apparently on the size of the animal and the kind and quantity of the food given. After the first day the amount of secretion obtained might vary, but on an average the twenty-four hour total fluctuated between 150 and 400 cc. of pancreatic juice.

There was a rather rapid increase in the buffering capacity of the secretion half an hour after the administration of a protein meal when compared with that obtained during fasting. The buffering capacity increased still further during the next two or three hours, the pH fluctuating between 6.02 and 5.81 after the addition of 1 c.c. of the acid. However, the material collected subsequently was not so capable a buffer, for the pH was rapidly lowered to levels between 3.22 and 2.65. These results suggested that the meat meal immediately stimulated the production of a large amount of pancreatic juice possessing considerable buffering power, and that later, after acidity in the duodenum had decreased, there was a corresponding diminution in the neutralizing substances present in the pancreatic secretion (Fig. 1).

The buffering power of the pancreatic juice after a carbohydrate meal was not so great half an hour after

Fig. 1. Titration curve (buffer value) of pancreatic juice at the end of one and seven hours following a protein meal.

eating as that developed following a protein diet. However, the neutralizing properties gradually increased until they reached their maximal value about one and a half hours after the ingestion of food. This efficiency was not maintained, as with a meat meal, and was gradually lost during subsequent observations. These figures revealed that it took a longer time to incite the production of buffering substances in the pancreatic juice and that they diminished sooner after developing their maximal potency with the carbohydrate meal than with a protein meal (Fig. 2).

The assimilation of a fat diet was followed by only a slight increase in the amount of the buffering substances present in the pancreatic juice a half hour after ingestion, but, by the end of one and a half hours, their value closely approximated that obtained with the other foods. However, owing to the fact that the acidity developed in the duodenum was not so marked as in the other instances, it was quite natural that the neutralizing power of the secretion should diminish rapidly during succeeding observations.

During fasting, although there was no stimulation or buffer substances in the pancreatic juice by food, the secretion still possessed some buffering power. Occasionally the characteristic buffering effect after the addition of the first few drops of hydrochloric acid could be detected, but in the majority of instances the pH was rapidly lowered to a rather uniform level.

#### COMMENT

The graphs representing the pH of the pancreatic juice after the various types of diets possessed several characteristics in common. When hydrochloric acid was first added to the secretion, the pH dropped rapidly, just as when water is added to acid. After a few drops, however, the action of the buffering substance soon became apparent, for the curves remained fairly

Fig. 2

Fig. 2. Titration curve (buffer value) of pancreatic juice at the end of one and seven hours following a carbohydrate meal.

level in spite of the increasing amount of acid present. When the neutralizing power of the pancreatic juice was finally exhausted, the pH rapidly proceeded to rather low levels, again quite similar to the result obtained by the addition of water to acid. The buffering value developed following each test meal was approximately the same, but the capacity of the secretion in this respect was lost more rapidly with the carbohydrate and fat meals than with the protein meal, probably as a result of the difference in the acid level produced in the duodenum by these various diets. Thus the results obtained during this experiment appeared to substantiate Elman's and McCaughan's findings, for the pancreatic juice was always alkaline even after continuous secretion for thirty-four days and when infection and leakage were known to exist. In addition the buffering value of the secretion was exceedingly high following the ingestion of all types of test meals.

## SUMMARY

An investigation was conducted on the properties of the pancreatic juice collected from pancreatic fistulas every half hour during fasting and after the ingestion of protein, carbohydrate, and fat test meals. A continuous secretion of pancreatic juice was noted at all times, provided there was no infection or leakage present. Protein diets stimulated a greater flow of secretion than any of the other test meals used. The amount of secretion depended largely on the size of the animal and the kind and quantity of food ingested. The buffering capacity of the pancreatic juice reached its maximum one to three hours after the ingestion of food and gradually diminished as the acidity in the duodenum decreased. The secretion was always alkaline and even possessed slight buffering power during fasting. When the buffering capacity was highest, 1 c.c. of pancreatic juice was capable of practically neutralizing an equal quantity of tenth-normal hydrochloric acid.

## Peptic Ulcer Following Loss of Pancreatic Secretion Through a Fistula: An Experimental Study

By

M. TISCHER HOERNER, M.D.  
ROCHESTER, MINNESOTA

WHILE studying the effect of exclusion of the pancreatic secretion on the content of the upper portion of the gastro-intestinal tract, it was noted that peptic ulcer developed in some of the animals in which the pancreatic secretion was excluded from the duodenum by a pancreatic fistula, whereas in no instance was an ulcer found in those animals in which the secretion of the pancreas was excluded by evulsion of the pancreatic ducts.

These observations are in accord with those noted by previous investigators. Many investigations have been made in which for one purpose or another the pancreatic ducts have been ligated or evulsed. In very

few instances have peptic ulcers been noted following this procedure even when the animals lived for many months after exclusion of the pancreatic secretion. It should also be noted that peptic ulcer is rarely found in depancreatized animals. On the other hand, as the investigations of Elman and Hartmann, Dragstedt, Montgomery and Ellis proved, loss of pancreatic secretion through a fistula is followed by the development of peptic ulcers in the duodenum in a very high percentage of experiments.

It is evident, in so far as the development of duodenal ulcer is concerned, that the loss of pancreatic secretion from the body causes some change which does not occur when the pancreas is prevented from secreting. On the other hand, as the results of my

Fig. 1

previous investigations show, exclusion of the pancreatic secretion from the duodenum by a pancreatic fistula and by evulsion of the pancreatic ducts causes almost identical changes in the reaction of the duodenal content. With these facts in mind it seemed desirable to determine whether there was any significant change in the reaction of the content of the upper portion of the gastro-intestinal tract associated with the development of the ulcer that occurs after draining the pancreatic secretion to the outside of the body.

#### METHOD

Gastric, duodenal, and jejunal fistulas, as well as combinations of such fistulas, were made according to the transposed loop of intestine method (3) and were utilized in obtaining specimens from the upper portion of the gastro-intestinal tract at half-hour intervals during an eight-hour period. The hydrogen ion concentration of such specimens was determined at once by the quinhydrone gold electrode and potentiometer. Samples were collected during fasting and following the administration of protein, carbohydrate, and fat test meals until representative figures were secured at the various levels for each dog used in the experiment. Pancreatic fistulas were then made according to the technic of Elman and McCaughan and the forementioned tests were repeated. The dogs were given 300 to 600 c.c. of physiologic saline solution intravenously every day, depending on the size of the animal and the amount of pancreatic juice secreted during the preceding twenty-four hours.

It was impossible to determine positively before necropsy whether an ulcer had developed. It was also impossible to know when an ulcer was in the process of formation. These difficulties were at least partially overcome by making repeated tests until the animal died or was sacrificed because of infection or because

Fig. 1. Variations in the pH of the gastric content in the fasting state, before and after establishing a pancreatic fistula and during or after the development of a duodenal ulcer.

leakage of the pancreatic secretion had occurred. The presence or absence of duodenal ulcer was determined at necropsy. The data were then assembled in two groups: those secured from the animals in which ulcer was present and those secured from the animals in which no lesion in the duodenum was present.

#### RESULTS

After the production of pancreatic fistulas in these animals no change in the reaction of the gastric content was noted during fasting or following the ingestion of protein, carbohydrate, or fat test meals. In the duodenal content, however, although the variation in the reaction during fasting was within normal limits, a low pH was more frequently obtained. Protein and carbohydrate test meals were followed by a more rapid lowering of the pH, and this low level was maintained for a longer period than in the normal dog. Similar changes were sometimes observed in the jejunum, but only after a protein diet.

Elman and Hartmann reported the development of duodenal ulcers in all of their dogs in which they had made pancreatic fistulas. In this investigation ulcers were found in only 42 per cent of the animals, but this high incidence appears to be of considerable significance. A comparison of the observations made on animals in which ulcer developed and on those in which the lesion did not develop showed that the development of ulcer was apparently accompanied by a very definite change in the reaction of the content at all levels of the gastro-intestinal tract that were examined. These changes began from six to fifteen days after making the pancreatic fistula. The reactions of the gastric, duodenal, and jejunal content of animals with peptic ulcers can be summarized as follows:

*Stomach.* As much as 15 c.c. of grayish mucoid material could easily be withdrawn from the fasting stomach at the time the ulcer appeared to be develop-

Fig. 2

Fig. 2. Variations in the pH of the gastric content after a protein meal, before and after establishing a pancreatic fistula and during or after the development of a duodenal ulcer.

Fig. 3

ing. These samples possessed an exceedingly low pH, fluctuating between 1.50 and 3.00. The gastric acidity had never been found to be maintained at such a level during fasting before the development of the ulcer or in animals in which ulcer was not found (Fig. 1).

The reaction of the gastric content after a protein meal was always quite high, so that the secondary increase in acidity was not so apparent as in the fasting state. It was quite evident, however, that a pH which often ranged between 1.50 and 2.00 was definitely lower than that found in previous observations (Fig. 2).

**Duodenum.** When a dog had a peptic ulcer, the pH of the duodenal content following a protein meal varied from 3.00 to 4.00, which was a somewhat lower level than was observed in animals in which ulcer was not present (Fig. 3). Under similar circumstances a definite increase in the duodenal acidity was also noted during fasting and after carbohydrate and fat test meals.

**Jejunum.** The reaction of the jejunal content, which is usually quite constant, showed changes in animals that had an ulcer (Figs. 4 and 5).

In the fasting state the pH of the content of the jejunum ranged from 4.50 to 6.00, with occasional lower readings in animals in which ulcer was found, instead of a pH of 7.00 or higher as is usually observed. At times as much as 7 c.c. of this gray or yellow-brown material could be collected, which was an unusual amount at this level of the intestine during fasting.

After a meat meal the jejunal content of these animals had a pH which varied between 3.50 and 5.00. Thus the increased amount of highly acid material from the stomach could not be neutralized as formerly, or its passage down the intestine was more rapid.

Carbohydrate and fat meals were followed by similar changes in the reaction of the jejunum, but they were not so marked as those observed after a protein diet.

Fig. 4. Variations in the pH of the jejunal content in the fasting state, before and after establishing a pancreatic fistula and during or after the development of a duodenal ulcer.

Fig. 3. Variations in the pH of the duodenal content after a protein meal, before and after establishing a pancreatic fistula and during or after the development of a duodenal ulcer.

### COMMENT

It is definitely shown by these investigations that the effect of the loss of secretion of the pancreas is not necessarily the same as the effect of preventing the gland from secreting. When pancreatic fistulas were established, thus eliminating the pancreatic secretion from both the duodenum and the body, duodenal ulcers developed in 42 per cent of the animals. However, when the pancreatic ducts were evulsed, thus likewise eliminating the pancreatic juice from the duodenum but without loss of the secretion, ulcer did not occur. It is difficult to explain why drainage of the pancreatic juice to the outside of the body was associated with the formation of peptic ulcers, and why elimination of the secretion from the duodenum by evulsion of the pancreatic ducts did not have a similar effect, because it is quite obvious that the slight difference in the reaction of the duodenal content resulting from the two procedures was not the significant factor involved.

In this regard it should be pointed out that, when the pancreatic juice was drained to the outside of the body, the fluid and sodium chloride were replaced in the form of daily intravenous injections of physiologic saline solution, but, that the other salts were entirely lost along with the secretion. On the other hand if the pancreatic ducts were evulsed, the fluid and basic salts were not lost but were retained in the body. This might account for the better condition and longer life of the animals following the latter procedure. Loss of certain constituents in the pancreatic secretion may be an important factor in the formation of the lesions. Nevertheless, whatever the correct explanation may be, it is safe to assume that the mere absence of the pancreatic juice from the duodenum was not the main element involved in the development of peptic ulcer.

The unavoidable variable conditions under which the observations were made make it hazardous to draw

Fig. 4

Fig. 5

definite conclusions. The results, however, appear to indicate that there was an increase in both the amount and acidity of the content of the upper portion of the gastro-intestinal tract in the animals in which ulcer was found. Whether these changes occurred before or after the development of the lesions could not be ascertained. Likewise it was impossible to determine whether or not these changes were dependent on some concomitant factor such as hemorrhage from the ul-

Fig. 5. Variations in the pH of the jejunal content following a protein meal, before and after establishing a pancreatic fistula and during or after the development of a duodenal ulcer.

erated surface. Often a small amount of blood in the stomach or duodenum will produce a change in the reaction of the content of the upper portion of the gastro-intestinal tract. It can be definitely stated, however, that loss of the function of the pancreatic secretion, in regard to neutralizing, buffering, and diluting the gastric chyme, is not the only factor responsible for the lesions.

### SUMMARY

Specimens of the content of the upper part of the gastro-intestinal tract of dogs were collected during fasting and after the administration of various diets. Following the production of a pancreatic fistula in these animals, no change in the pH of the gastric content was detected, but the duodenal pH during fasting was more variable and after ingestion of protein and carbohydrate meals a lower value was reached and was maintained for longer periods than normally. The latter observation was sometimes noted in the jejunum after a protein diet. Peptic ulcer occurred in 42 per cent of the animals in which a pancreatic fistula was made. There appeared to be an increase in the amount of material obtained from the stomach, duodenum, and jejunum during fasting and after different test meals, as well as an increase in the acidity of the material, in the animals in which ulcer was found at necropsy.

## ABSTRACTS

MANN, FRANK, AND BOLLMAN, JESSE L.

*Jaundice. A Review of Some Experimental Investigations. J. A. M. A., 104:371, Feb. 2, 1935.*

All methods for the production of jaundice experimentally have one thing in common, that is, the production within the animal of more bile pigment than is eliminated by the liver at the same time. True hemolytic icterus as seen in the human being has not been produced experimentally in animals. The jaundice that follows complete removal of the liver is of the hemolytic icterus type. Obstruction of the common bile duct or injury to the liver produces a jaundice which might be called hepatic.

The results upon the animal of the jaundice depends on three factors: The effect of the retained bile on the body cells, the effect of the alteration of the bile or its absence in the intestinal tract, and the effect of the liver injury which accompanies the jaundice. Of these factors the loss of bile from the intestinal tract has been the only one carefully investigated. Complete loss of bile is compatible with life for an indefinite period but adequate care and a suitable diet are necessary.

There is a marked tendency for jaundiced animals to develop peptic ulcers. Perforation of an ulcer is the chief cause of death of animals with complete obstructive jaun-

dice. There has been no increase in gastric acidity in these animals. It is thought that the jaundice reduces the resistance of the gastric and duodenal mucosa.

The addition of meat to the diet of dogs with complete biliary obstruction of more than three months duration will usually result in death in less than a week, but they will live for months on a diet of milk and syrup.

Usually after three months of complete obstructive jaundice the feedings of meat or beef extractives will produce rapid formation of ascites. Resumption of original diet will cause the ascites to disappear.

Bile pigment continues to be formed after the removal of the liver. Hemoglobin is undoubtedly the material from which it is made. The main site of bilirubin formation in the mammal seems to be in the bone marrow.

No important function has been ascribed to bilirubin.

Bile salts must be formed in the liver because after its removal no bile salts can be detected in the blood or urine.

Complete biliary obstruction reduces the bile salts excreted in the urine by one-half of that found in normal animals with biliary fistulas. Further injury to the liver reduces this amount in the urine and blood until they may disappear entirely.

## SECTION III—Nutrition

### Protection of Nutrition During the Use of "Elimination Diets"

By

ALBERT H. ROWE, M.D.\*  
OAKLAND, CALIFORNIA

I HAVE always stressed the importance of assuring the proper intake of proteins, calories, vitamins and minerals in the "elimination diet" (1) which is taken for more than a week. I agree with Alvarez and Fineburg and others that absolute assurance of such a balanced diet is not necessary if the restricted diet has to be followed for only a few days. But in many definitely food sensitive patients, it is not possible to uncover the causes of their allergy rapidly, and diet trial must be continued for weeks or months until a diet which best relieves their allergy is obtained.

It is especially important to protect the patient against undesirable weight loss. Therefore where weight is low, patients must be told that they must eat plenty of the calorie carrying oils, sugars, and starches in their prescribed diets. Fortunately most patients maintain weight without such emphasis on calories. If weight tends to fall, it is wise to advise from one to four teaspoonfuls of prescribed oil in various foods with meals, and the same amount after meals to be taken as cod liver oil would be. In some cases, even more oil can be ingested without digestive disturbance. In addition, if attention is given to the inclusion of as much sugar and prescribed carbohydrate as the patient can tolerate, weight reduction can be prevented in practically all cases. If weight declines in spite of the physician's advice, it is practically certain that the patient is not cooperating in taking the requisite calories or that former habits of eating, lack of appetite, or indigestion prevent him from so doing. In such cases, I feel that a continuation of the "elimination diets" is not warranted, and that a general diet should be resumed, even though symptoms from allergy producing foods continue.

Emphasis moreover must be given to the necessity of assuring a proper protein intake. With milk, egg, and fish out of the diet, it is wise to insist that the patient take meat in fairly liberal amounts in some form at each meal, as suggested in the menus for my diets. McCollum (2) and McLester (3) especially have stressed the fact that a low protein intake over a long period results insidiously in decreased resistance to disease, lessened mental and bodily efficiency and stamina, early senility, and even in lessened fertility. Youmans (4) has reported internal edema, swelling of ankles and lowered serum proteins which

result from a low protein diet. In general there is an unfortunate prejudice against the ingestion of ample animal proteins which prompted Mosenthal and Boldman (5) recently to suggest an educational campaign to teach the public the importance of adequate animal protein in the routine diet.

The necessity of assuring a liberal intake of vitamins is more generally realized. The "elimination diets" which exclude milk and egg are moderately deficient in Vitamin D, which requires its addition in cod liver oil or halibut oil, or in viosterol. If natural or artificial sunlight is available, Vitamin D will be built up in the skin, making such vitamin therapy unnecessary except in the winter months. If fish is not in the diet, and especially if the patient is sensitive to cod liver oil, and sunlight is not available, then viosterol is necessary. Such viosterol is best prescribed in an oil which is included in the diet. Thus cottonseed sensitive patients should not take viosterol dispensed in cottonseed oil, and the same applies to corn sensitive patients with corn oil. Mead, Johnson and Company is preparing a viosterol in a soya bean oil for my patients who are on cereal free diets. Viosterol put up in sesame oil would also be suitable. Moreover, Vitamin D can be obtained through the use of irradiated foods. Since irradiated milk is not available to most food sensitive patients, at least at the start of their diet trials, it is advisable at times to irradiate certain foods, such as cereals or oils included in the patient's diet by exposing such foods under an efficient quartz light.

If the patient takes fairly liberal amounts of vegetables and fruit, a proper intake of Vitamins A, B, D, and G is probably assured. However, some children dislike and refuse vegetables, either because of whims or underlying allergy. Others refuse or have allergic reactions to many, and at times to all fruits. In these cases, the inclusion of yeast will take care of a deficiency in Vitamins B and G. It must be realized that yeast allergy rarely does occur, and at times is associated with positive skin tests to yeast. For a deficiency in A arising from inability to take green vegetables, especially carrots, spinach, and peas, the use of Carotene obtained from carrots may be indicated. In allergy, proper intake of Vitamin A seems important, since it may help to assure the integrity of the epithelial structures. If allergy exists to citrus fruits and a fair intake of green vegetables, especial-

\*Lecturer in Medicine, School of Medicine, University of California. Chief of Allergy Clinics at Alameda County and St. Mary's Hospitals.

Submitted May 2, 1935.

ly of tomato is not ingested by the patient, deficiency of Vitamin C may occur. In rare cases, the taking of ascorbic acid ( $C^6H^8O_6$ ) may be indicated. This has been prepared from limes, and seems to be identical with Vitamin C, .01 gr. of it equalling 30 cc. of orange juice. With such attention, latent avitaminosis will be prevented. I agree with Alvarez (6) however, that the recent overemphasis of vitamin therapy for commercial advantage is to be discouraged.

Finally, with a milk free diet, there is usually a slight calcium deficiency, especially if liberal amounts of calcium carrying vegetables are not consumed. Sherman (7) has shown that from .7 to one gram of calcium in the diet is needed every day. He has stressed the fact that the average American dietary is deficient in calcium, and that a proper amount preserves the characteristics of youth and that it is essential for the proper growth and normal metabolism. Thus the addition of one-half to one dram of a calcium salt is advisable. Bernheim (8) and others feel that it is best absorbed during digestive rest, between meals or on retiring. The use of dicalcium phosphate supplies phosphorus as well as calcium in a ratio approximating that demanded by the body. Tribasic calcium phosphate serves the same purpose and is less expensive. Calcium gluconate and calcium lactate have also been recommended to supply necessary extra calcium. However, as an inexpensive source of calcium, calcium carbonate is of value. Sherman, in a personal communication, states that finely ground carbonate should be as effective, though more slowly absorbed than calcium lactate.

It must be pointed out moreover that important elements in foods, especially in fruits and vegetables other than vitamins and minerals, probably exist which

are not recognized today. Of interest is the recent emphasis of unsaturated fatty acids in body economy, as pointed out especially by Evans and Lepkovsky (9). The realization that chronic dietary deficiencies produce serious disturbances has been stressed by Minot (10) in an excellent article. He points out the importance of including the dietary history in every patient's record. This should include the habits of eating from childhood, the actual amounts of milk, egg, meat, vegetables, and fruits eaten through the years, together with the habits of exercise, walking and work, and the amount of strain, tension, or relaxation which have been routine.

These suggestions about the adequate and balanced diet have been offered to aid physicians who are using diet trial, and especially the "elimination diets" for the diagnosis and treatment of food allergy. Deficiencies are not apt to occur if the suggestions and detailed menus for the "elimination diets" and especially those for the revised ones (11) are accurately followed. Care must be taken not to eliminate foods to which dislikes or apparent idiosyncrasies exist which are the results of nervousness or prejudices. In such neurotics many foods are unjustly suspected and unwarranted limitations may be so numerous that very unbalanced and harmful diets result. Such diets may also occur when foods are eliminated on the basis of positive skin reactions. In these patients who are suspected of true allergy, it may be necessary however to exclude many separate foods or groups of foods during the diagnostic period. In such cases, care about the adequate inclusion of protein, calories, vitamins and minerals discussed in this article will prevent metabolic injury which might otherwise occur.

## ABSTRACTS

RUTH GILBERT AND M. B. COLEMAN, Albany, N. Y.

*Undulant Fever in New York State. Jour. Infect. Dis. Pages 305-312.*

Investigations into the incidence of porcine and bovine strains of *Bacterium abortus* in cases of undulant fever suggest a variable occurrence. In New York State, cattle or dairy products are the source of the infection in nearly all cases.

There has been a rising incidence of this disease for several years, but even so investigators doubt that a tenth of the cases which occur are recognized.

Symptoms of undulant fever vary greatly in severity and in nature. Six deaths have been reported by these

workers in the 400 cases studied. Some patients are acutely ill for months; others are always ambulatory. Clinical manifestations included chills, or chilly sensations; a remittent type of fever, with a slow pulse rate, fatigue, loss of weight, and constipation; diarrhea occasionally; headache; pain in the back; acute abdominal attacks; pains in the joints; and pulmonary symptoms. Slight anemia, with leukopenia and relative lymphocytosis, was common.

A large percentage of the patients infected have had no contact with cattle, but have drunk raw milk and cream.

General, efficient pasteurization of milk in New York State is urged.

C. W. SCULL AND RALPH PEMBERTON.

*The Influence of Dietetic and Other Factors on the Swelling of Tissues in Arthritis; Preliminary Report. Ann. Int. Med., 8:1247, April, 1935.*

Scull and Pemberton, in a series of selected cases, have been able to show that the subsidence of swelling of tissues, pain and limitation of motion is accompanied by a net loss of water from the body. The authors are lead to suggest that disturbances of water distribution in tissues constitute significant factors in the dynamic pathologic changes of the rheumatic syndrome. In evaluating the role of dietetic and other factors they have found that the administration of several types of low calorie diets is associated with a net loss of water and with clinical improvement. Dehydrating diets, adequate in calories, high in protein, low in fluid and high in fat induced a net loss of water from arthritic patients with clinical evidence of improvement, and the suggestion is made that the relative increase of fat and protein metabolized on low calorie diets exerts a significant influence in the striking clinical effects frequently achieved. Recumbent rest is considered as acting, in part, by favorably influencing a shift of fluid from the tissues to the blood and lymph channels. Many seemingly unrelated factors which influence arthritis favorably when used within proper limits, such as dietetics, recumbent rest, heat and massage, may act in part by favoring fluid removal from tissues. Attention is directed to the fact that a negative water balance contributes to recovery from both atrophic and hypertrophic arthritis. This suggests that both types of arthritis arise, in part, from similar or comparable premises; and further, that rigid restriction of many therapeutic measures, especially those here mentioned, to one type alone is unwarranted. The relationships pointed out do not imply that dehydrating measures alone constitute a therapeutic escape from arthritis. Vigorous sweating, purgation or diuresis have long been known to be of only limited value, and even dangerous. So far as changes in the distribution of tissue fluids in arthritis may be desirable, they should be achieved by the more sustained and "physiological" influence and measures discussed by the authors. Further justification is afforded for the controlled use of dietetic measures in the treatment of arthritis. The reader is again cautioned as to the dangers involved in uncritical employment of this agency.

Samuel Morrison, Baltimore.

JOHN M. FLYNN, M.D.

*The Changing Cause of Death in Diabetes Mellitus. (From the Medical Clinic of the Peter Bent Brigham Hospital, Boston).*

The records of all the cases of diabetes mellitus dying in the Peter Bent Brigham Hospital between its opening in 1913 and the commencement of the insulin era in 1923 were analyzed with the following summarized conclusion:

1. "The annual mortality of new cases varied so much from year to year as to make conclusions with regard to the value of treatment, as it affected the hospital mortality of diabetes during any one year, of but little value.

2. Diabetes became less severe as the age at which symptoms were first recognized became greater, although increasing years did not necessarily preclude a severe form of the disease.

3. There were four common causes of death. These were: (a) Coma, with or without terminal infection; (b) Sepsis; (c) Cardiovascular renal disease, including gangrene; (d) pulmonary tuberculosis."

There were 562 cases admitted from 1913 to the end of 1922 and 49 died in the hospital. From 1923 to 1933, 917 cases were admitted and 66 died in the hospital. The mortality rate of the pre-insulin period was 9% and that of

the post-insulin period 7%. The most striking feature to be observed in a comparison of the two groups of cases is that fatalities in the younger age group now appear to be much less frequently met with than formerly. The previous study showed 21 deaths in persons below their 40th year, whereas the present study shows but 7 or in terms of percentage, 38% of the deaths in the earlier series occurred in patients below 40, while but 14% of the younger cases in the present series have been fatal. This is due to insulin.

In the age group from 61 to 80 the average duration of life was 8.1 years in the earlier series and 5.7 years in the present study. Two striking differences are to be seen between the fate of the pre-insulin diabetic and the diabetic of today. Deaths from coma, sepsis and tuberculosis have shown a marked decrease, whereas those due to cardiovascular disease and its sequelae have shown a marked tendency to rise. Among the conclusions drawn are that cardiovascular disease has shown an increase in frequency; unusual complications have remained practically unchanged. The mortality rate of new cases of diabetes in this clinic has decreased from 9% prior to the introduction of insulin to 7% during the period of insulin therapy. The present tendency is for coma and sepsis to be eradicated. Our present mode of treatment appears to have no effect upon the form of cardiovascular disease which is seen in diabetic patients.

SPIES, TOM D.

*The Treatment of Pellagra. J.A.M.A. 104:137 (Apr. 20, 1935).*

It has been recognized that the prognosis in the patient severely ill with pellagra is exceedingly grave. The mortality rate in such a group of cases treated in the hospital with highly nutritious diet and yeast was 54 per cent. More recently a second and larger series of such cases showed a mortality of only 6 per cent. The striking difference in mortality rate is the reason for the present paper.

The therapeutic measures the author stresses as important in this paper are as follows:

Adequate professional and nursing care. A diet of 4000 calories a day must be given.

Yeast is highly efficacious in the treatment, 75 to 100 grams daily in the powder form. This may be given in divided dosage.

Ventriculin in doses of 200 grams daily is just as effective as yeast and easier to take.

Wheat germ in 250 to 300 grams is also efficacious in the treatment.

Liver extract orally or parenterally may be used. Parenteral liver extract is used when the patient is dangerously ill.

Stomatitis and glossitis quickly improve as the condition improves.

Tincture of opium is useful in the treatment of the diarrhea.

Vomiting must be treated by frequent small feedings. Abdominal pain if it is not due to surgical condition can be controlled by tincture of opium.

Nervous system involvement and peripheral neuritis require sedatives and special care in feeding to keep the nutrition up.

Anemia is handled with diet and in other cases with large amounts of iron.

Dermatitis is treated with mild antiseptic solutions used as soaks or on sponges.

Relapses must be watched for after return to health. The patients should be seen at least once a month to make sure that they are taking and assimilating an adequate diet.

Francis D. Murphy, Milwaukee.

BERGER, EDMUND H., AND BINGER, MELVIN W.

*The Status of the Kidneys in Alkalosis. J.A.M.A. 104:1383 (April 20, 1935).*

The authors discuss seven cases treated for peptic ulcer with the use of alkali in whom definite symptoms and chemical evidence of alkalosis developed.

The symptoms complained of in this group of cases were distaste for milk, anorexia, nausea, and vomiting, weakness, nervousness, mental confusion, dull steady headache, polydipsia, polyurea, numbness and tingling, cramps, and in several instances tetany.

The carbon dioxide combining power of the blood ranged from 69 to 84 volumes per cent.

The authors stress that the condition comes on slowly and that it is relatively uncommon.

They stress that the status of kidney function be carefully checked before alkaline powder therapy is used. If kidney impairment exists, alkaline therapy will probably be unsatisfactory.

Mucin or tribasic calcium phosphate may be used in some of these cases advantageously.

The question of renal damage from prolonged use of alkali therapy is not settled.

In five out of the seven cases here discussed evidence of impaired renal function was present after the alkalosis had been adequately controlled.

Impaired renal function is important etiologically in alkalosis and must be given consideration before instituting alkali therapy in peptic ulcer.

Francis D. Murphy, Milwaukee.

MACKIE, THOMAS T., AND HENRIQUES, MADELEINE.

*Ulcerative Colitis. II-Deficiency States. J. A. M. A., 104:175 (Jan. 19, 1935).*

In a group of seventy-five consecutive cases of ulcerative colitis varying in degree from mild localized proctitis to advanced and extensive involvement of the entire colon, forty-seven cases showing indications of deficiency states were encountered.

The most common manifestation was the change in the mucous membrane of the tongue. This was found in forty-six patients.

Changes in the buccal mucosa were noted in four patients. Abnormal skin conditions were found in eleven cases.

Blood chemistry changes were noted in seven cases. Three of these patients showed inversion of the albumin-globulin ratio and extensive edema.

In thirty-nine cases anemia was present.

Peripheral neuritis occurred in one case.

The author feels that deficiency states are important factors in the pathologic physiology of ulcerative colitis.

Francis D. Murphy, Milwaukee.

ALICE BERNHEIM AND J. H. GARLOCK.

*Parathyroidectomy for Raynaud's Disease and Scleroderma. Department of Surgery, Cornell Med. School, Ann. Sur., Vol. 101, No. 4, April, 1935.*

As a result of observations which cover a number of years the authors have formed the opinion that disturbances in calcium metabolism are factors in the development of Raynaud's Disease and other vasospastic conditions. Calcium deficiency in the diet, common in adults and producing a negative calcium balance, may cause in certain individuals an abnormal sensitiveness to vasospasm. In patients with thrombo-angiitis obliterans, Raynaud's Disease or arteriosclerosis, vasoconstricting stimuli as cold, worry, fatigue, over-exertion and tobacco may produce pain, undue coldness, intermittent claudication and discoloration of the extremities.

It is not known exactly how disturbances in calcium metabolism produce the various manifestations of vasospas-

tic conditions. The constitutional factor must play an important role since it is observed that individuals react differently to disturbance of calcium metabolism—some may show merely a vasospasm of peripheral vessels as in Raynaud's Disease, while others may show a generalized or localized scleroderma. Others show nephrolithiasis or nephrocalcinosis while in others the change may be due to changes only in the bony skeleton producing generalized decalcification.

The authors point out that the proper understanding of the rationale for parathyroidectomy in these conditions begins with the assumption that one of the functions of the parathyroid glands is to maintain a constant serum calcium level of about 10 to 10.5 mgs. per 100 cc. With long deficiency in calcium intake the glands become hypertrophied as a result of thin increased physiological activity in withdrawing calcium from the bones to the blood.

Many such patients will respond favorably to an adequate calcium intake but the authors feel that if there is no amelioration of symptoms, parathyroidectomy should be resorted to. They give case histories of six patients who failed to respond to increased calcium intake and who showed spectacular and immediate amelioration of symptoms following removal of one or two of the parathyroids. They found that the removal of one or more of these glands did not result in a compensatory hypertrophy of those remaining. No post-operative tetany was observed due to adequate pre and post-operative calcium administration.

Charles T. Sturgeon, Los Angeles.

MACKIE, THOMAS T., AND POUND, ROBERT E.

*Changes in the Gastro-Intestinal Tract in Deficiency States. J.A.M.A. 104:613 (Feb. 23, 1935).*

In studying a group of seventy-five cases of ulcerative colitis, deficiency states of varying degree were found in sixty-three per cent of the group. A history of defective dietary was seldom elicited. Too rapid a passage of food constituents through the intestinal tract or abnormalities of the small intestine producing defective absorption of the product of digestion was given possible etiologic significance.

Roentgenographically, changes were demonstrated in twenty-nine out of thirty-seven cases of chronic ulcerative colitis. Edema of the mucous membrane, disorganization of motor activity and hypotonicity of intestinal musculature could account for the changes noted radiographically.

The suggestion is made that these changes in the small intestine are related to the deficiency states and perhaps play a part in their development.

Francis D. Murphy, Milwaukee.

REDVERS, THOMPSON, Quebec, Can.

*Elimination of Brucella Abortus With the Milk of "Carrier" Cows. Jour. of Infect. Dis. Pages 6-11.*

Knowledge of the group of organisms classified under the generic name of Brucella has been accumulated since its discovery thirty-six years ago. Interest has been directed toward a study of its natural habitat, modes of dissemination, and control of the infection which it produces. So far the infection must still be considered in the same category as tuberculosis.

The milk of ten high-producing cows, which never manifested clinical symptoms of infectious abortion, but whose blood serum showed significant agglutinins for Brucella abortus was examined for the presence of Brucella abortus at intervals of thirty days over an entire lactation period.

The study demonstrated that Brucella abortus may be constantly eliminated with the milk of cows classified as "healthy carriers."

J. Arnold Bagen, Rochester, Minn.

## SECTION IV—*Roentgenology*

### Diaphragmatic Hernia: with a Report of Ten Cases of Oesophageal Orifice Hernia\*

By

KATHERINE S. ANDREWS, M.D.  
BOSTON, MASSACHUSETTS

#### HISTORY

THE first description of any type of hernia through the diaphragm is that of Ambrose Paré (1) who described two traumatic hernias in 1610. Thirty-six years later, Fabricius Hildanus (2) described another traumatic case, and 1698 Riverius (3) described the first congenital diaphragmatic hernia. Morgagni (4) wrote the first monograph in 1769, and in 1824 Sir Astley Cooper (5) added an account in his "Treatise on Hernia." From 1853, when Bowditch (6) presented 88 cases from the literature, there has been a slowly, but steadily growing interest in diaphragmatic hernia as attested by the numerous papers appearing in both English and foreign literatures. However, it was not until 1903 that the first case of para-oesophageal hernia was described by Andrew (7): this hernia was discovered during a post-mortem examination in the dissecting room of the Aberdeen university. In recent years, improved methods of radiographic technique demonstrated by Berg and Akerlund and their associates, have made it possible to study this condition with accuracy and have added considerably to our knowledge of it.

#### INCIDENCE

The incidence of diaphragmatic hernia is hard to determine since there is great discrepancy in published reports. According to Arnsperger (quoted by Folk-enord) (8), prior to 1908 the diagnosis had been made only ten times on living persons. In 1915 Kienboech (9) reported 3 cases diagnosed and confirmed by necropsy and MacMillan (10) (1920) found 3 cases in 15,000 radiographic examinations in United States Army General Hospital No. 1. Rendick (11) reported 2 cases in 5033 clinical examinations in Bellevue Hospital. From the year 1920 on, larger series of cases have been reported. L. B. Morrison (12) reported 42 cases out of 3500 (1925) gastric cases studied. Pancoast and Boles (13) report (1924) 16 cases (one traumatic) out of 9000 gastro-intestinal examinations. Akerlund (14) reported 30 new cases in 1926, and Ritvo (15) reported 60 cases observed over a period of five years. In the Mayo Clinic (16) from 1900-1925, 30 cases were recognized and 19 were confirmed

at operation. From 1925-1933, 147 cases were recognized, and 60 patients operated on; *i. e.*, five times as many cases in last 8 years as in preceding 24 years. In 1931 Hedblom (17) again summarized the literature and tabulated 1435 cases, 190 of which were hernias of the oesophageal hiatus. From these reports it is obvious that the incidence of diaphragmatic hernia in the literature is increasing rapidly, probably because it is now possible with improved radiographic methods to demonstrate the presence of these hernias more easily. Some radiologists believe the presence of small oesophageal orifice-hernias to be a normal occurrence in advanced age. Schatzki (18) found them in 22 out of 30 random subjects between the ages of 65 to 83.

#### DEFINITION AND CLASSIFICATION

Hernias of the diaphragm must be distinguished on the one hand from eventration of the stomach, and on the other from thoracic stomach. In the former, the diaphragm is abnormally high, but the stomach always lies below it. In the latter, the stomach always lies above the diaphragm, and the oesophagus does not pass through it, the opening usually occupied by the oesophagus being occupied by the duodenum. (Le-Wald (19)). In diaphragmatic hernias, the abdominal organs may be found at times above the diaphragm, and at times below. Almost any abdominal organ may participate in diaphragmatic hernias: the colon, liver, pancreas, spleen, but in the majority of cases the stomach alone is implicated.

Hernias of the diaphragm have been variously classified. Richards (20), 1923, has classified them from an embryological point of view as being "true" hernias or "false" hernias,—the true hernias being those with a hernial sac, and the false those without a sac. These, again, he subdivides into congenital and acquired hernias. 90 per cent (he states) of all cases are "false" hernias.

Ritvo (15) classified diaphragmatic hernias into "congenital" and "acquired," the congenital hernias being due to maldevelopment of the diaphragm, or to the delayed descent of the stomach, and the acquired hernias being due to an increase in intra-abdominal pressure. By other observers, they are classified as "traumatic" or "non-traumatic" hernias. But as Harrington has pointed out the numerous classifica-

\*From the Gastro-intestinal Clinic of the Boston Dispensary and the medical service of Dr. Joseph H. Pratt.  
Submitted, May 17, 1935.

tions are of academic interest only and it is difficult or impossible to distinguish them clinically.

### ETIOLOGY

The importance of an embryological factor in the etiology of these hernias has been stressed by numerous writers. The consensus of opinion seems to be that in congenital hernias there must be either a delayed descent of the stomach from the thorax with simultaneous shortening of the oesophagus, or else a maldevelopment of the diaphragm, with improper fusion of its parts, or with abnormality in the muscle fibres themselves. Ritvo (15) 1930, has discussed these points in detail and more recently Morrison (21) *et al.* (1934) have done likewise. In the acquired hernias there is thought to be some underlying weakness of the musculature which makes it possible for an increase in intra-abdominal pressure such as is present in pregnancy, constipation, obesity, even though the pressure be not great, to force the abdominal organs into the chest cavity.

Non-traumatic herniation may occur theoretically in any of the normal openings of the diaphragm, but actually most hernias present themselves through the oesophageal opening. Ritvo (15) states that hernias through the vena cava or aortic opening are unknown, and Healy (22) points out that this is probably true because the oesophageal opening is the only muscular one in the diaphragm, the others being made up of tendinous attachments.

*Hiatus Hernias:* In 1911 Eppinger (23) in his comprehensive monograph on the diaphragm reported 635 non-traumatic diaphragmatic hernias, and found 55 of these to occur through the right dome of the diaphragm, and 11 through the oesophageal opening. But, more recently, Akerlund (14) has demonstrated oesophageal "hiatus hernias" to be 6 or 7 times as frequent as all non-traumatic diaphragmatic hernias combined. The improved radiographic technique advocated by Försell and his school recently has made it possible to verify the accuracy of Akerlund's observation. The 10 cases reported below fall entirely into this group of oesophageal orifice hernias.

Akerlund (14) classified all such hernias through the oesophageal orifice in 3 groups, on an anatomical basis.

1. Oesophageal hiatus hernias with congenital shortening of the oesophagus.
2. Oesophageal hiatus hernias without congenitally shortening of oesophagus in which the oesophagus does not form part of the hernia. (*i. e.*, Para oesophageal hernias.)
3. Oesophageal hiatus hernias in which the oesophagus is not shortened but in which the distal portion of the oesophagus is a part of the hernia contents.

Of these three the last group is the most common, the first the least common.

### SYMPTOMS

Oesophageal orifice hernias do not always present symptoms, it is now well understood. The growing literature on the subject from radiologists, indicates that many small hiatus hernias, discovered in the course of routine examination for other conditions, are entirely without symptoms. This is apt particularly to be true in advanced age as emphasized by Schatzki (18). When these hernias do present symptoms they may be of two types, *i. e.*, those with *symptoms referable to the abdomen*, and those with *symptoms refer-*

*able to the thorax*. The case histories reported below, illustrate in detail the symptomatology as presented by our group.

*Pain or abdominal discomfort* (often limited to the epigastrium) was present in all our cases except two (Cases V and VII). There was no definite time-relation of pain to food, and no constant relief by food; indeed eating usually aggravated the discomfort. It was sometimes severe (as in Cases VI and X) but was usually not severe. Pancoast and Boles (13) note, in their study, that pain may be so severe as to simulate biliary colic, and may have the same radiation. It may be even excruciating enough to suggest angina pectoris (Case VI). It is easily conceivable that such might be so when the hernia is held fixed in the oesophageal opening. The most significant fact about pain in our series was that it often had a postural relation, and sometimes could be relieved by assuming the upright position.

*Dysphagia* was noted in three of our cases (Cases I, VIII and X). Wagner (24) has emphasized it in his study, as has also Healy (22). *Nausea and vomiting* were outstanding symptoms in seven of our ten cases and had very definite relation to position. In Case V the statement that vomiting could be affected by bending forward led to the clinical diagnosis before radiographic studies were made. *Ereuctations of gas* (Cases III, IX and X), and *regurgitation* (Cases VII and VIII) were noted less frequently. *Hæmetemesis* or *melenæ* was not noted in any instances, though Hedblom (17) gives bleeding as a symptom in 8 of his 229 cases.

Of *thoracic symptoms*, palpitation was an outstanding symptom in Case IV and *dyspnea* in Case I. These cardio-respiratory symptoms seem most likely to occur when the hernia is large or well filled, or when there is associated cardiac disease such as aortitis or cardio-sclerosis. *Cough* was noted (Cases I and III) and has been emphasized as occurring especially in children by Truesdale (25); it is apt to occur in paroxysms and is non-productive.

Ulcers of the stomach either in the herniated portion, or in the stomach below the hernia, or in the duodenum have been described by Key (26), Harrington (27), Kransjö (28) and others. In these cases the symptomatology of peptic ulcer may dominate the picture. We observed none of these in our group.

*Secondary anemia* in association with ulcer and hiatus hernia has been noted by Gardener (29) and others, but it has also been noted in patients without demonstrable erosion or ulceration as Bock (30) has recently pointed out. Case X illustrates this fact.

### DIAGNOSIS

As has been intimated, the diagnosis of this condition is made by radiological examination. However, familiarity with the clinical picture sometimes may lead one to suspect the presence of hiatus hernia. In Case V the presumptive diagnosis was made by the clinician and confirmed by the radiologist only by having the patient bend forward several times, thus forcing the sac to protrude above the diaphragm and to fill with barium. The story of symptoms which come and go with change of posture seem to us very suggestive. Truesdale (25) recently has (1931) pointed out that clinicians usually fail to consider the possibility of hiatus hernia in differential diagnosis.

**Differential diagnosis:** The case histories appended indicate the chief conditions to be considered in the differential diagnosis. *Oesophageal obstruction* from organic disease is suggested by the dysphagia of Case I, for instance. Case VI, in its periodicity, time-relation of symptoms to, and relief by food, makes one think of *peptic ulcer*. The picture presented by Case V might well be ascribed entirely to a *neurosis*; and that of Case X to *gall-bladder disease* with stones. As is noted, severe *cardiac disease* is suggested by the history of Case VI. These last two possible conditions, *i. e.*, *cholelithiasis* and *angina pectoris*, are the affections most likely to be confused with incarcerated hernia of the oesophageal orifice. It should be emphasized, perhaps, that as one becomes more and more familiar with the clinical picture of hiatus hernia, it assumes the aspects of a definite symptom-complex which can often be suspected by the clinician even before it is confirmed by radiologic examination.

**Röntgen Data:** The best radiological technique for the examination of the patient seems to be that in which the patient is examined in both prone and erect postures, and turned freely from side to side, and from front to back, while under the fluoroscope. Observation while the diaphragm is held in deep inspiration often is helpful. Important in establishing the diagnosis and in differentiating hiatus hernia from epicardial dilatation of the oesophagus, is the tracing of the mucosal folds of the stomach into the herniated sac. This can best be done by studying with the "relief" method of Forsell and Berg.

### TREATMENT

It must be emphasized that many hiatus hernias require no special treatment, since many, especially in older people, it now appears, are asymptomatic and are discovered only in the course of routine examination. However, others do produce symptoms, as in the cases cited, and an effort must be made to give relief. Medical treatment often will suffice. This consists chiefly in diet. Small frequent feedings of easily digested food have been most helpful in our group. An effort should be made to eliminate those food-stuffs which ferment easily or cause the production of gas. In Germany, carbonated waters have been given in an attempt to balloon-out the fundus of the stomach and so prevent its herniation. Our own results in this respect have not been successful. It is important to instruct the patient to maintain the erect posture for an hour or two after each meal. Associated conditions, such as ulcer and anemia, must receive their usual treatment. In those cases unrelieved by a medical regime, or in those patients presenting severer symptoms, surgery must be resorted to. Incarceration always calls for immediate surgery.

The approach in surgery may be either through the thoracic cavity or by the abdominal route. Both methods give good results in the hands of experienced surgeons. Truesdale (25) in 1931 reports 12 cases of diaphragmatic hernia (9 children and 3 adults) operated on by the thoracic method with only one death,—that in an adult from pneumonia on the seventh post-operative day. And in 1934 he reported on six cases of the oesophageal orifice type operated on by the transthoracic approach without a fatality. (25) Hedblom (17) in 1925 studied 378 operated cases of her-

nias through the diaphragm, nineteen from the Mayo Clinic, and the rest from the literature. Of 126 operations for acute incarceration, sixty-seven died (mortality 53%); and of 252 without incarceration fifty-nine died (mortality 23.4 per cent). Harrington (31), up to November, 1928 had only one death (from pneumonia) in 21 cases. In 1929 he reported fourteen more cases (32) operated upon by laparotomy with two deaths, one from cardiac and one from pulmonary complications. Some of these cases reported were cases of hernias following injuries (such as automobile accidents), so, that one might expect a higher mortality than in operations of election.

Phrenectomy, phrenicotomy, or phrenic emphraxis are sometimes used as palliative measures or as preliminary measures for operations in these cases. Harrington (32) feels that the pumping action of the diaphragm is an important factor in producing the symptoms. Phrenectomy paralyzes the diaphragmatic muscle and stops this pumping action. Also by these means nerve communications are destroyed, which destruction prevents reflex cardio-spasm, and shoulder pain. Key (26), as early as 1924 advocated neurectomy as a cure for ulcers associated with diaphragmatic hernia in an effort to mobilize the diaphragm and so reduce bleeding and symptoms. Goetze (33) seems to have been the first to simplify suturing of the diaphragm by chilling of the phrenic nerve with ice (done in children) in 1925. Two years later Lemons (34) suggested phrenic neurectomy as a preliminary measure in more radical operations. In 1929 Harrington (32) reported three cases in which he had excised the phrenic nerve with some success. These advances in surgery indicate that one should not hesitate to resort to operation in cases in which the symptoms persist in spite of medical treatment.

### SUMMARY

1. Herniation of the stomach into the chest cavity is discussed with special emphasis upon the hernias of the oesophageal orifice.
2. Ten cases of hiatus hernia are presented in the hope that they may serve to make clearer the symptomatology of this not uncommon condition.\*

### CASE REPORTS

**Case 1.**—G. G. Aged 44. American. Janitor. This patient was well until four years before admission. At that time he first developed a sense of discomfort under his sternum which he described by saying "it seems at times as though the food does not have time to go down to the stomach," or, "it seems as though there is a ball in my stomach which moves up and down." This "ball" he stated rose in his throat and often choked him when he was eating, and at such times he grew very short of breath, the discomfort became more severe, and at times amounted to actual pain which was located under the sternum and about both costal margins. Usually when the pain occurred it came on about a half hour after eating and lasted several hours. Sometimes it awakened him at night. It was not relieved by food or by soda, but at times it was relieved by aromatic ammonia. In addition to these symptoms he stated that he was sometimes awakened from sleep by fits of non-productive coughing, and a sense of suffocation. These symptoms he could always relieve by getting up and walking about. There were various other

NOTE: In each case reported, the radiologic diagnosis was made by Dr. Alice Ettinger. I wish to express my appreciation to Dr. Ettinger for her help and for her permission to reproduce the roentgenograms.

Fig. 1. Case II.

unrelated symptoms such as dizziness, insomnia and headache.

PHYSICAL EXAMINATION showed a rather stocky man, apparently in good health, with wide spread lesions of scabies. The heart and lungs were apparently entirely normal. Blood pressure was 134/80. Examination of the abdomen revealed slight tenderness in the epigastrium and in the right upper quadrant. Knee jerks and pupillary reflexes were normal.

Urinalysis was normal.

Hinton test was negative.

Blood count was 4,625,000 red cells per cubic millimeter and 9,300 white cells; 96% of hemoglobin (Sahli), and a normal differential.

Gastric analysis (Ewald meal) showed no free hydrochloric acid, but a total acidity of 25.

Stool examination for occult blood was negative.

Orthodiagram showed slight enlargement of the heart to the left.

Electrocardiogram was reported as normal.

*Roentgenogram* of the gastro-intestinal tract revealed a walnut size dilatation at the lower end of the oesophagus, obviously not an epicardial retention, but a herniation of the stomach mucosa through the oesophageal opening.

COMMENT: This patient's description of his symptoms is most graphic. His paroxysms of nocturnal coughing and suffocation, it is interesting to note, were relieved by assuming an erect posture.

Case 2.—K. C. Aged 67. Canadian. Coal Miner. This patient came in to the clinic complaining of a burning sensation under the sternum which radiated upward toward his neck, and which had been present intermittently for ten or twelve years. It came on chiefly at night time, sometimes awakening him from sleep and being always definitely worse when he was in the recumbent position. Associated with the substernal burning there was often a feeling of nausea but no vomiting. There was also at times slight difficulty in swallowing, even liquids causing distress. There was no time relation to meals and no relief by ingestion of food. He had found, however, that he could obtain definite relief by bending forward and regurgitating his last meal.

PHYSICAL EXAMINATION was essentially negative, except for some sclerosis of the peripheral arteries and some shortening of the right leg, due to an old injury.

Urinalysis was normal.

Hinton test was negative.

The blood count was normal.

Gastric analysis showed free acid of 61, a total acidity of 73.

Stool examinations were negative for occult blood.

A *roentgenogram* of the gastro-intestinal tract revealed an orange-sized herniation of the stomach through the oesophageal hiatus. This was observed almost immediately and was seen in both upright and recumbent positions.

COMMENT: The relation of this patient's symptoms to posture is striking, as is the fact that he could relieve himself by bending forward and regurgitating food. Note also slight dysphagia.

Case 3.—C. W. Aged 74. American. Housewife. This patient's symptoms began twenty years ago. They consisted chiefly of epigastric discomfort which came on one to one and a half hours after meals, or in the early morning. It was located immediately below the xiphoid and did not radiate. It did not occur after every meal or even every day, but in the twenty years there had been no periods of distinct remissions and no periods of long relief. At the time of admission the distress was distinctly less troublesome than it had been four years before. In the earlier years vomiting usually accompanied the burning sensation, the food coming back in small quantities and in an undigested state. In recent years, however, vomiting had been less troublesome. Eructations of gas occurred also at times. All these symptoms, she stated, were most likely to come on when she was lying down. She suffered from no other distress, except a slight, non-productive cough present only occasionally. Sixteen years before admission, a gastro-intestinal series was reported as showing a herniation of the stomach through the diaphragm; four years before another gastro-intestinal series was reported as showing a gastric ulcer on the posterior wall. Two subsequent radiographic examinations, however, did not reveal the ulcer.

PHYSICAL EXAMINATION showed an extremely well preserved woman with early cataracts in both eyes. The heart and lungs were entirely normal. Blood pressure was 154/88. The abdomen was tympanitic to percussion, but otherwise entirely natural. The pupillary and knee reflexes were normal.

Urinalysis was normal.

Hinton test negative.

There was 92% of hemoglobin; 4,700,000 red blood cells; 7,300 white blood cells and a normal differential count.

Fractional Ewald meal showed a fasting achlorhydria but at the end of sixty minutes free acid reached 46 with a total acidity of 62.

Stool examinations were negative for blood by the benzidine test.

*Gastro-intestinal Roentgen* series showed an apple-sized herniation of the stomach mucosa through the oesophageal opening. There was also a diverticulum about the size of a walnut on the inferior surface, near the duodenal-jejunal flexion. The examination was otherwise negative.

Laboratory studies showed a blood sedimentation rate of 19 millimeters at the end of one hour.

COMMENT: This patient may well illustrate that group of cases in which hiatus hernia and peptic ulcer are associated. It makes clear the difficulty of differentiating these two conditions on a basis of history alone.

Case 4.—J. G. Aged 65. Jewish. Housewife. This patient was admitted complaining of palpitation, and "pains about her heart," and discomfort in the epigastrium. These had been present about a year. Palpitation came on in attacks without relation to exertion, appearing often while she was sitting at rest. With the palpitation she suffered at times, moderate or severe pain under the

Fig. 2. Case IV.

sternum and over the praecordial region. This, together with the pounding of her heart, had been severe enough and terrifying enough to make her call a doctor on two occasions; hypodermic medication was given for relief. There was no dyspnea while walking on a level, nor on climbing one flight of stairs and the patient slept comfortably with one pillow. No history of cough, nor of peripheral oedema. In addition to these symptoms, she complained also of some epigastric burning and discomfort relieved by soda bicarbonate. This, was not marked, had no relation to meals, and was not associated with nausea or vomiting. Constipation was troublesome. There was a loss of ten pounds in weight in three years. Vision, she said, was slowly failing.

**PHYSICAL EXAMINATION** revealed an elderly, gloomy woman with cataracts in both eyes, coated tongue and a lipoma above the right clavicle. The chest was emphysematous in type but the lungs were clear on physical examination. Examination of the heart showed it to be slightly enlarged to percussion, the right border measuring 2 centimeters and the left 13 centimeters from the mid sternal line. The rate was 98, and the rhythm showed frequent extra systoles; there were no murmurs; A2 was accentuated and the quality of the sounds was only moderately good. Blood pressure was 150/85. Peripheral blood vessels showed moderate sclerotic changes. Except for a small umbilical hernia, the abdomen was not remarkable. Both legs had small varicosities but the reflexes were normal.

Urinalyses were normal except for a trace of albumin. Hinton test was normal.

Blood count showed 80 per cent of hemoglobin, with 3,900,000 red cells and 7,700 white cells. Differential count was normal.

Stool examination was negative for occult blood.

Electrocardiogram reported T-wave flattened in all leads, and the regular interposition of ventricular extra systoles.

An orthodiagram showed the heart slightly enlarged with the aorta widened and tortuous.

A Graham Test reported the gall bladder to be normal.

A *gastro-intestinal Roentgen* series showed a hernia about the size of an apple through the oesophageal orifice. It was otherwise entirely normal.

**COMMENT:** This patient illustrates well the group of symptoms referable to thoracic organs which may be produced by hernias through the oesophageal opening. Electrocardiogram and orthodiagram demonstrate the presence of some organic changes of the cardio-vascular system, but the history of attacks suggests that the protrusion of the stomach into the chest space and may have initiated the cardiac symptoms.

**Case 5. J. R. Aged 68. American. School teacher.** This patient gave a confused story with multiplicity of complaints. Chief among these were symptoms referable to her joints and to her gastro-intestinal tract. Almost constant dull, aching pain in her knees, followed an accident in 1923, resulting in removal of a semi-lunar cartilage. Roentgenograms of the knees showed proliferative changes about the joint with narrowing of the joint spaces. A diagnosis of chronic arthritis was made and among other therapeutic measures a diet was prescribed. She then began to complain of vomiting, stating she could not eat fruit, fish, eggs and various other foods without vomiting immediately. There was little discomfort and no pain associated with this. The vomiting came on almost always after she went to bed. She stated that she could invariably produce it by bending forward. Bowels had a tendency to be loose; averaged seven or eight stools a day. Her dietary history was one of irregularity and inadequacy, but there had been no loss of weight.

**PHYSICAL EXAMINATION** was essentially negative except for Heberden's nodes on the fingers and some limitation, and crepitation, on motion in both knees.

Urinalyses were normal.

Laboratory studies showed negative blood serology.

Blood count showed 100% hemoglobin, 4,890,000 red cells; 6,675 white cells, and a normal differential count.

Gastric analysis showed free hydrochloric acidity 53, total acidity of 84.

Stool examinations were negative for occult blood.

Sensitization tests were entirely negative.

A psychological examination revealed an eccentric personality but no psychosis.

*Gastro-intestinal roentgenograms* at first seemed normal, there being no evidence of hernia in a recumbent position

Fig. 3. Case V.

or in deep inspiration. She was then asked to bend forward, and immediately afterward the hernia was visualized, with normal stomach mucosa easily recognized in it. The rest of the examination was entirely negative.

COMMENT: In this case it is obvious that all the patient's complaints cannot be due to the hiatus hernia; however, her history of vomiting only in a recumbent position, or after bending forward can easily be explained by the hernia.

Case 6.—S. D. Aged 60. Italian. Scissors grinder. This patient, about two months before admission, while climbing the stairs to the elevated railway, was seized with a very severe pain in his chest, chiefly under the sternum but also along the left costal margin. He had to be taken home and put to bed, where he remained about two weeks. Since that time he has had a number of similar attacks of severe substernal pain. These, however, were not always related to exertion, but came on at times, he insisted, soon after eating. The pain was paroxysmal in character; it had no time-relation to food, was not relieved by food. It has been severe enough to make him call a local physician. In addition to the attacks of severe pain he complained of "stomach trouble" which has been present on and off for ten years. By this he meant a feeling of discomfort in the epigastrium and under the sternum which came on one or two hours after eating and was relieved a little by food or by soda. There were no nausea and no vomiting with this. Some eructation of gas, no loss of weight. No symptoms referable to any other system.

PHYSICAL EXAMINATION showed an excitable, elderly, Italian man with marked dental caries and pyorrhea and moderate sclerosis of the peripheral blood vessels. On examination of the heart, the apex beat was not seen or felt in any position. The right border measured 2 centimeters and the left 12.5 centimeters from the mid sternal line; the sounds were of good quality, the rhythm was regular, the rate was 72, no murmurs were heard. Blood pressure was 156/84. Lungs were entirely negative. The abdomen was natural.

Urinalyses were normal.

Hinton test was negative.

Blood count showed hemoglobin (Sahli) 95 per cent, 11,000 white cells, 4,705,000 red cells, and normal differential count.

An Ewald Meal reported normal motility with a free hydrochloric acid of 50 and a total acidity of 77.

Graham test was normal.

An electrocardiogram showed beginning partial A-V block, but no evidence of coronary disease.

An orthodiagram showed the heart moderately enlarged in all diameters (consistent with arterio-sclerotic heart disease.)

A roentgenogram of the chest showed the lungs clear, but the heart definitely enlarged to the left.

A *gastro-intestinal Roentgen* series reported definite herniation of the stomach mucosa about the size of a walnut through the oesophageal opening. It was otherwise entirely normal.

Vital capacity tests ranged from 2500-3000.

COMMENT: At first it was thought that this patient suffered from two distinct types of pain and discomfort; the first severe and paroxysmal in character, possibly due to angina pectoris, the second less severe, relieved by foods and alkalies, of longer duration, probably related to his hyperacidity and herniation.

Laboratory studies were thought to support these diagnoses. However, subsequent observation of this patient over a period of a year and a half has made the diagnosis of angina pectoris seem less likely. This seems to be true because of the lack of response to nitro-glycerine, and be-

Fig. 4. Case VII.

cause exertion does not produce the attacks of pain but indeed he insists sometimes it actually relieves them. In view of these facts it is difficult to decide whether or not any of this patient's severe pain was due to heart disease or whether it was due to temporary incarceration of the herniated stomach. If anginal in character, may it not have been produced in an already diseased heart by reflex disturbance from the protrusion of the stomach into the chest cavity?

Case 7.—E. C. Aged 36. American. Housewife. This patient entered the hospital for the draining of a small abscess in the breast. In the course of routine study her urine was found to be strongly positive for sugar and her blood sugar contained 444 mg. of glucose per 100 c.c. (not fasting). She was placed upon a diabetic regime and improved until she was discharged with a fasting blood sugar of 190 mg. While in the hospital she was discovered to have a blood tinged mucous vaginal discharge. Pelvic examination resulted in a diagnosis of carcinoma of the fundus and treatment by radium was recommended. This was done and she continued to have deep x-ray therapy from that time to the present. Four years later she re-entered the clinic because she felt tired and because she had been having "indigestion." This consisted of attacks of mild vomiting or regurgitation of a few mouthfuls of dark colored liquid. They were not associated with pain or nausea and were never severe. They almost always came on in the morning, after a good night's sleep. There was also dull pain across the lower back. Otherwise history was unimportant.

PHYSICAL EXAMINATION showed a woman with pale skin which was loose, flabby, suggesting recent weight loss. Her lungs were clear throughout. Her heart was normal in size to percussion, the rhythm was regular, rate 90, sounds of good quality, no murmurs were heard. Blood pressure was 134/70. The abdomen was relaxed and flabby and there was slight tenderness in both lower quadrants. Knee jerks were active, extremities showed marked varicosities.

Laboratory studies reported blood sugar varying from 246 to 222, with sugar in her urine, but no acetone or dia-

Fig. 5. Case VIII.

cetic acid. There was also a small amount of albumin, no casts or red cells.

Blood serology was positive.

Hemoglobin was 84 per cent. Red Cells were 4,490,000; white cells 7,100.

Blood sedimentation rate was 19 millimeters in one hour.

A *gastro-intestinal Roentgen* series revealed a moderate sized hernia through the oesophageal opening, demonstrable only in the recumbent position. There was no sign of malignancy nor any other organic lesion.

COMMENT: In view of the patient's diagnosis of malignancy four years before the onset of her gastro-intestinal symptoms, it was at first feared that these might be due to metastatic lesions from her original growth. The presence of the hernia demonstrated by roentgenogram, however, seemed to account for her gastro-intestinal symptoms.

Case 8.—P. O. Aged 74. American. Stableman. This patient was admitted complaining of epigastric distress and vomiting. He was well until five years before when during his meal or immediately afterward he began to have a slight distressed feeling in his epigastrium followed by vomiting. These symptoms did not trouble him much at first, but in the year previous to admission they had become progressively worse, so that he then had almost daily vomiting: He described this by saying, that a few minutes after beginning his meal he would have a sudden return to his mouth of food just eaten; he would vomit this out, then return to the table and finish his meal in comfort. There was no nausea at all, and no pain—only a vague sense of discomfort. The food came up in a rush, and consisted only of that eaten a few minutes before. In addition he stated that at other times the food seemed to stick in his throat and “did not want to go all the way down.” There was no loss of weight. There were no other gastro-intestinal symptoms and no symptoms referable to any other system.

PHYSICAL EXAMINATION showed a rather healthy looking old man with no evidence of recent loss of weight. The lungs were entirely clear. The heart to percussion was slightly enlarged to the left; there were frequent extra

systoles; the rate was normal; the sounds were of good quality and there were no murmurs. Blood pressure was 120/80. Examination of the abdomen was entirely negative. Deep reflexes were normal.

Urinalyses were negative.

Blood serology was negative.

Blood count showed hemoglobin being 95 Per cent, red cells 6,000,000 and white cells 11,000.

Stool examinations were negative for occult blood.

The Graham Test done twice with the double oral method, showed no filling.

A *gastro-intestinal Roentgen* series showed a hernia the size of an apple through the hiatus opening. It was otherwise entirely negative.

Non-protein nitrogen was 30 mg. per 100 cc.

COMMENT: Although, the Graham Test showed no filling, his symptoms were not thought to suggest gall-bladder disease.

Case 9.—H. D. Aged 62. Irish. Housewife. This patient for the past twenty-five years had been troubled with attacks of vomiting which came on almost immediately after eating. These were accompanied by a sense of discomfort in the epigastrium, but by no actual pain. There were eructations of gas. The vomiting came on without nausea and without warning. There was no relation of the attacks to meals and no relief by eating food. Before admission the attacks had been so severe as to make her consult a physician, who sent her to the hospital for study and treatment. In the hospital she was placed on a soft diet and advised to see a surgeon immediately. After leaving the hospital she continued on a soft diet, and felt greatly improved, being without distress or vomiting. She stated that she had gained 8 pounds in the previous months. There were no other symptoms referable to any other system.

PHYSICAL EXAMINATION revealed a well nourished Irish woman with good spirits. Lungs were entirely clear. The heart was normal to percussion; the rate was 74; the rhythm regular; no murmurs were heard. Peripheral blood vessels showed moderate sclerosis and blood pressure

Fig. 6. Case IX.

was 170/105. There was very slight tenderness in the epigastrium, but otherwise the abdomen was negative. Varicosities were present in both lower legs; deep reflexes were normal.

Urinalyses were negative except on one occasion when a slight trace of albumin was found.

Laboratory studies showed a negative blood serology.

Blood count showed 93 per cent hemoglobin, 4,985,000 red cells, 9,700 white cells, with a normal differential count.

Stool examination showed no occult blood in the Ben-zidine test.

The *gastro-intestinal Roentgen* series revealed a herniation of the stomach about the size of an apple through the oesophageal hiatus, in which mucosal folds could be easily traced. This hernia was seen only with the patient in a recumbent position, since in the upright position no hernia could be demonstrated.

COMMENT: It is interesting that the patient was so completely relieved of symptoms by small, frequent meals of soft food. One notes too the need to examine these patients in recumbent as well as in upright positions.

*Case 10.*—M. R. Aged 47. Irish. Housewife. This patient, five years before admission, in the middle of the night, was seized with severe knife-like pain in the left chest and in the epigastrium, which radiated through to the mid back. Pain lasted for several hours. It was associated with much nausea and vomiting. The vomitus contained only the food eaten the night before, and none from the preceding meal. This attack gradually subsided under the care of a local physician and although there was an occasional dull ache in the area described, she had no further attacks until two years ago. In this second attack she again had severe pain and vomiting and a priest was called to anoint her, as she thought she was going to die. She then remained free from pain and vomiting until about two weeks before admission to the clinic. Since that time she has had occasionally sharp intermittent, cramp-like pain in the left lower chest. This was associated with some eructations of gas, but it had no relation to food and

was not relieved by food. About two years before she first noticed slight difficulty in swallowing solid food, and also even in swallowing liquids at times. There had been no significant weight loss and the rest of the history was unimportant, except for a history of increased dyspnea, brought on by exertion or excitement, and of some oedema of the ankles in the evening.

PHYSICAL EXAMINATION revealed a small, under-nourished woman with rather marked pallor of the mucous membranes and an icteroid tinge to the skin. The heart measurements were normal, the rate was 80, the rhythm was regular, the sounds were of good quality; however, there was a loud systolic murmur heard over the entire cardiac area, but heard best at the pulmonic area. No diastolic murmur was heard. Blood pressure was 100/60. The lungs and abdomen were entirely negative to examination. Pelvic examination showed a firm mass, thought to be intramural myoma. There was also felt an enlarged slightly tender mass in the region of the left ovary.

Urinalyses were normal.

Wassermann test was negative.

Blood studies were interesting since they showed a severe grade of anaemia, the hemoglobin by Sahli method being 30 per cent, the red cells 3,320,000, and the white cells 6,700. Differential count was normal. Reticulocyte count was 1%. The average red cell diameter was 7.18 microns.

Stool examinations on meat free diet were negative for blood.

A gastric analysis done with histamine, showed no free acid in any specimen.

Blood sedimentation rate was 14 millimeters in one hour.

Radiographic examination of the gastro-intestinal tract was entirely normal except for small herniation of the stomach through the oesophageal opening.

Graham Test was entirely normal.

COMMENT: This patient's story might well suggest the presence of gall-stones. A temporary incarceration of the hernia is thought to explain her attacks of severe pain.

## SECTION VI—*Abdominal Surgery*

### The Use of Metal Clips in Gastrointestinal Anastomosis\* An Experimental Study

By

RALPH B. BETTMAN, M.D.†

and

LEO M. ZIMMERMAN, M.D.††

CHICAGO, ILLINOIS

THE ease and rapidity with which metal skin clips may be applied in the closure of skin incisions has suggested the possibility of finding a similar method for approximating the stomach and bowel. E. Wyllys Andrews, (1), in 1911, reported the use of modified skin clips in the inner row of intestinal anastomoses in clinical surgery. He added that "in the lumen of the bowel these need not be absorbable, as they fall into the canal later." The problem has received scant consideration since these pioneer observations were made.

In our approach to the question, we wished to determine whether a single row of Michel skin clips applied to the mucosal surfaces might not adequately approximate the edges of the stomach or bowel for the formation of gastrointestinal anastomoses. With this method we hoped that broad serosal coaptation could be obtained, the clips on the inner surface would probably slough out and be discharged, the permanent burying of foreign suture substances would be avoided and the formation of a flange or shelf would be minimized. We were interested specifically in determining the feasibility and safety of the method, whether it permitted saving in time and operative work, if adequate hemostasis could be secured, what the immediate post-operative course would be, the subsequent fate of the clips, the reaction of the tissues and the gross and microscopic healing at the line of anastomosis.

#### EXPERIMENTAL METHODS

In order to answer these questions, we performed a series of gastroenterostomies and of partial gastric resections in a number of dogs. The operations were done under ether or intravenous nembutal anesthesia, with the usual aseptic precautions. Because of the length and mobility of the duodenum, this portion of the gut, rather than the jejunum, was usually used for anastomosis with the stomach. In most of the operations, the loops to be anastomosed were approximated and incised in the usual manner, and the clips

placed first on the posterior limb of the stoma. After rounding the "corners", the portion already closed was depressed and the edges to be united were everted to permit the placing of further clips. The last 2 or 3 cms. of the stoma could not, of course, be closed in this fashion. In some of the animals an interrupted suture or two was used; in others, clips were placed on the serosal surface, turning in the cut edges. In the latter, no attempt was made to bury the clips. In another group of animals, a gastrotomy incision was made on the anterior wall of the stomach, and through this incision the anastomosis between bowel and posterior stomach wall was effected from within the stomach cavity. In some instances, an oval window was cut in the posterior wall of the stomach to provide a circular stoma instead of the usual slit-like opening. This technique permitted more accurate apposition of the edges to be united and minimized the flange at the site of anastomosis. The gastrotomy incisions were closed either by suture or by a row of clips placed on the serosal surfaces, inverting the cut edges. The abdominal wounds were closed in layers and the animals were returned to their cages. Water by mouth was permitted on the day of operation, and food as soon thereafter as desired by the animal. A diet of kitchen scraps was maintained for the duration of the experiment. The animals were sacrificed and post-mortem examinations made at intervals ranging from three days to six months.

#### RESULTS

It was soon found that, in the dog, it was feasible to perform gastrointestinal anastomoses by the use of a single row of Michel clips applied in the manner described. After the first few attempts, the mortality in simple gastroenterostomy was practically nil, although it was material in the gastric resections. However, a parallel series of experiments, in which a single row of catgut sutures was used instead of the clips gave a practically identical mortality rate. This seemed to indicate that whenever the total gastric content was forced to leave the stomach through the artificial stoma, the danger of the operation was greatly increased, regardless of whether clips or sutures were used. Death from hemorrhage was not observed in

Fig. 1

any of the experiments. While recognizing the fact that the danger of hemorrhage in the dog is in no way comparable with that in man, the total absence of demonstrable postoperative bleeding in our animals indicated that hemorrhage from the cut edges was adequately controlled by the clip technique. On several occasions, when a larger blood vessel was severed, bleeding was promptly stopped by placing a clip over the spurting vessel. The operative time and effort were strikingly reduced by the clip method. The immediate convalescence, as a rule, was excellent. The animals were alert and active within a very few days, ate freely of a mixed diet, and remained well-fed and in good condition until they were sacrificed.

When this work was begun, we anticipated that the clips placed on the mucosal surfaces would quickly become loosened and fall into the lumen of the bowel. We were rather surprised to find, at reoperation or autopsy at varying intervals after the operation, that many of the clips were retained, and that frequently they were imbedded in the tissues. The persisting clips seemed to be very well tolerated and gave rise to no ulceration or marked inflammatory reaction. The stomata remained patulous and apparently functioned well. In fact, it seemed to us that in some specimens the stomata were held open by the ring of clips. It is entirely possible that this persistently patent circular stoma might have definite advantages over the usual potential, slit-like one resulting from suture anastomoses.

In the animals sacrificed at varying periods following operation, the peritoneum was found to be smooth and free, with a minimum of adhesions about the anastomosis. Even in those instances in which the last portion of the anastomosis was closed with clips placed on the serosal surfaces, there were relatively few adhesions. As can be seen in the photographs, the healing, both at the serosal and the mucosal surfaces was strikingly smooth. Microscopically, after

Fig. 1. Serosal surface at site of gastrointestinal anastomosis showing freedom of scar tissue.

healing had occurred, the mucosa of the stomach passed over into that of the duodenum, without interruption. A minute, scarcely detectable wedge of scar tissue, alone, marked the site of anastomosis. Nowhere was there evidence of inflammation or infiltration. Even about the retained clips, there was very little evidence of foreign body reaction.

#### SUMMARY

Summarizing our results, the experiments thus far have shown that, in the dog, gastrointestinal anastomoses can be made with a single row of metal clips placed on the lumen side of the structures to be united. The operation is very quickly done, with little operative trauma. *Bleeding is easily controlled; convalescence is rapid, and the condition of the animals remains good.* Many of the clips, instead of being extruded, as had been anticipated, remain in place and become firmly imbedded in the tissues. Gross and microscopic healing is very satisfactory, with a minimum of adhesion and inflammatory reaction at the site of anastomosis.

#### EXPERIMENTS WITH ABSORBABLE METAL CLIPS

Believing that the retention of the clips might be objectionable in provoking irritation or ulceration, an attempt was made to find an absorbable substitute for the Michel clip. Search for absorbable metal suture materials has been made from time to time by several investigators. In 1878, Dr. E. C. Huse, (3), an American, recommended magnesium ligatures, stating that he had used them three times. E. W. Andrews, (2), working in this laboratory some 20 years ago, studied the absorbability, flexibility and tensile strength of various metals and their alloys, hoping to be able to

Fig. 2

Fig. 2. Duodenum opened showing stoma of duodeno-gastrostomy. Stoma is held open by ring of clips.

Fig. 3

use them for deep sutures and ligatures. His search for an absorbable metal sufficiently flexible for these purposes was unsuccessful. Seelig (4) studied the properties of commercial metallic magnesium with the same end in view, but found it too brittle. He succeeded, however, in securing chemically pure magnesium wire which was sufficiently strong and pliable to serve as suture material. Such sutures absorbed readily and were tolerated remarkably well both locally and systemically. Unfortunately, in the process of absorption, oxidation of the magnesium occurred, with the liberation of hydrogen gas, which absorbed at a rate somewhat slower than it was formed. The resultant gas cysts separated the tissues at the line of suture, and were considered of sufficient significance to prohibit the employment of magnesium sutures in surgery.

We felt that this objection would not maintain if the magnesium were used in the form of clips applied within the lumen of the bowel, since, with such application, only the point of the prong is buried. At this point we wish to express our appreciation of the very generous assistance rendered us by the American Magnesium Corporation, which provided us, without expense, with ribbons of pure metallic magnesium of suitable width, thickness and flexibility for making into clips. It was soon found that exact reproductions of the Michel type clip could not be made of this material, because even the softer grades of the metal were too brittle to permit the punching out of prongs. However, a satisfactory substitute was found in a simple curved band sharpened at both ends, and having the general shape and size of the Michel clip. These were sufficiently flexible for use in our experiments, although much more care was required in placing the clips, since, if compressed too tightly, they tended to break in the middle. Properly applied, their tensile strength and elasticity were sufficient to hold the anastomosed structures in apposition.

With these clips we performed a series of experiments similar to those described with the German silver clips and with similar results so far as mortality, convalescence and control of hemorrhage were concerned. The clips were found to absorb with striking rapidity. Wounds inspected after 3 or 4 days revealed extensive, irregular corrosion of the clips, sufficiently advanced to break some of them. After 7 days only fragments of clips were left, and these vestiges disappeared between the 10th and 14th days. Clips placed on the serosal surfaces were absorbed at a much slower rate than those within the lumen of stomach or

Fig. 3. Cross section at site of gastro-duodenal anastomosis.

bowel. Gas cysts were noted occasionally about retained prongs of magnesium, varying from minute size to 4 or 5 mm. in diameter. They were much more evident about clips placed on the serosal surfaces. No untoward effect could be ascribed to these small gas-cyst accumulations about clip ends.

Healing was very satisfactory in these experiments. Seelig, in the studies mentioned before, was impressed with the absence of leucocytic infiltration or other evidence of reaction to buried magnesium. We were able to confirm this observation. Nor were there systemic effects which could be attributed to the magnesium. The fragility of the clips, and their rapid absorbability, however, were construed as possible sources of danger. In other respects, the absorbable clips seemed to adequately fulfil their purpose in the experiments.

### GENERAL SUMMARY

Gastroenterostomy and enteroenterostomy can be safely performed in dogs by using a single row of German silver Michel clips placed on the mucosal surfaces of the structures forming the stoma. This method greatly reduces the time and operative work required. Bleeding can be adequately controlled, and the post-operative convalescence is rapid and uneventful. Healing is very satisfactory, with a minimum of reaction and scar formation. These non-absorbable clips, instead of being sloughed into the lumen of the bowel, tend to become imbedded. This retention of metallic foreign bodies is theoretically objectionable, although no injurious effects were seen in the experimental animals. On the other hand, the ring of clips served

Fig. 4

Fig. 4. Microscopic section of site of gastrointestinal anastomosis.

to hold the stomata open. From the standpoint of function, such a patulous opening might have real advantages over the potential, slit-like stoma of usual suture anastomoses.

Absorbable metal clips made of pure metallic magnesium may be used with apparently the same degree of effectiveness and safety. These clips are more fragile, and therefore, somewhat more difficult to apply.

They are rapidly absorbed within the gastric or intestinal lumen, and obviate the theoretical objection of retained metallic bodies at the line of anastomosis. On the other hand, the early dissolution and fragmentation of the clips may constitute an additional hazard.

This work is purely experimental in character, and no attempt has been made to apply it clinically.

## ABSTRACTS

FRANK L. MELENEY, M.D., New York, New York.

*"Zinc Peroxide in the Treatment of Microaerophilic and Anaerobic Infections."* *Ann. Surg.*, Vol. 101, No. 4, April, 1935.

The author presents case histories of six patients who had chronic, ulcerative, burrowing, non-gangrenous lesions of the abdominal wall apparently due to a "micro-aerophilic hemolytic streptococcus." Three of these patients were treated locally with zinc peroxide, with remarkable responses.

The organism obtained from these wounds and sinuses was a streptococcus which had anerobic tendencies but which was not a true anerobe, however, for on subsequent artificial cultivations, it gradually became more and more capable of growing aerobically. They therefore classified it as a "micro-aerophilic hemolytic streptococcus." Vaccines and Besredka filtrates made from this organism did not yield good results and improvement was always followed by discouraging retrogression.

The preference of the organism for an anerobic environment suggested the use of a peroxide to inhibit its activity. Zinc peroxide was used because of its ability to yield oxygen over a relatively long period of time rather than give it off abruptly.

A creamy suspension was made with zinc peroxide in sterile water or with gelatine or as in one case, with a 5 per cent pyrophosphate solution which suspends the heavy powder better than gelatine and does not favor the growth of other organisms. This suspension was then applied to the ulcerative surface of the wounds and injected deep into the sinuses with the result that in a few days when cultures were made of these wounds, the microaerophilic hemolytic streptococcus was no longer found, but in its place was a green aerobic streptococcus. This occurred in two of the three cases treated with zinc peroxide and the author is of the opinion that the original organism had become changed or dissociated in the wound following the use of the zinc peroxide. Following this treatment the patients felt better, their fever subsided and the wounds began to heal. The rolled in margins were trimmed away and soon it was possible to plant some skin grafts which in each case grew nicely and fused and the wound soon completely healed.

The author states that in his search of the literature he was unable to find any adequate description of this disease which he states begins gradually and is characterized by the following course. What appears to be an ordinary drainage tract from a deep or subcutaneous abscess fails to follow the usual course of healing. Improvement which may have been present in early stages of the injection gradually ceases. The skin margins become undermined with liquefaction of the subcutaneous fat and connective

tissue. There is no gangrene of the skin but the edges roll in. The undermining progresses and the skin opens widely, exposing a base of gelatinous, pale granulation tissue. In one or more places, in the neighborhood of the lesion, the skin will take on a dull red, or bluish appearance. It is then found that the undermining has extended beneath this area and the skin has become thinned out as if it were being liquefied from beneath. After a number of weeks a small opening appears in this thin area. This secondary opening gradually enlarges and the margin may extend until it fuses with the original ulcer. In lower abdominal lesions the undermining frequently spreads down toward the groin or toward the pubic region, extending into the vulva, or into the scrotum, or beneath the crease of the groin into the thigh. In these regions it may extend inward, dissecting beneath the muscles and forming deep sinuses into the pelvis.

The lesion is usually only moderately painful but the pain may be excruciating. Fever develops daily with temperature rises to 101 and 103.

After months or years of suppuration the lesion may gradually heal spontaneously, or burrow deep and produce death either by erosion into a large vessel or by the gradual development of amyloid degeneration of the liver, spleen and kidneys.

Although this disease is relatively rare, the author notes that its chromacity and its severity are indicative of its importance.

BALFOUR, D. C.

*Principles of Gastric Surgery. Surgery, Gynecology and Obstetrics, Vol. 60, No. 2A, February, 1935, pp. 257-263.*

In the Murphy Memorial lecture for 1934 the author reviews the history of gastric surgery and shows that it is based on a foundation of physiological knowledge, exact pathological classification of lesions, accuracy of diagnosis, better understanding of the indications for operation, more intelligent application of operative procedures, and established principles of technique. He laments the fact that in only one out of four cases of cancer of the stomach can resection be attempted, when first seen by the surgeon. If resection cannot be done, the exclusion operation of Devine should be performed. Gastroenterostomy has a small place in the treatment of gastric cancer; should marked or prolonged improvement follow this operation it would constitute evidence that the growth could have been removed.

The most effective treatment, both in respect to maintaining low mortality and low morbidity, and increasing curability depends on the following factors: first, pre-operative overcoming of the effects of dehydration; second,

pre-operative cleansing of the stomach by lavage; third, anaesthesia adequate to allow satisfactory examination of the growth, and possible detection of metastases; fourth, wide removal of the growth and a segment of the duodenum, together with as nearly complete as possible extirpation of lymph nodes; and last, such restoration of gastrointestinal continuity that the anastomosis not only will function well, but in the event of recurrence it will most likely ensure protection against obstruction of the gastro-intestinal tract. The chief problem concerning ulcers, which still awaits solution, concerns the cause. The management of duodenal ulcer, and the indications for operation, are relatively well understood and generally practiced. Concerning gastric ulcer there is no such harmony of opinion. That an apparently benign gastric ulcer may undergo malignant change is generally agreed, but the frequency with which such a change takes place is a subject of considerable difference of opinion. Should some method become available to distinguish clinically these lesions the benign ulcer could be treated medically without the ever present fear and humiliation of attempting to cure a malignant lesion by diet and alkalis.

The dictum that if the gastric ulcer does not yield promptly to medical treatment it should be classed as a lesion other than ulcer, should be adhered to strictly.

MOSHER, H. P.

*The Esophagus. Surgery, Gynecology and Obstetrics, Vol. 60, No. 2A, February 15, 1935, pp. 402-417.*

The author reviews the work done on the esophagus in Boston, and gives the Boston point of view.

Webes of the esophagus occur usually in the upper part, and are very frequently associated with the exostosis of the cervical vertebrae. The treatment of such conditions is to excise a portion of them, and to periodically dilate the esophagus by means of bougies.

Pouches in the esophageal wall at the level of the bifurcation of the trachea are not uncommon. They are due to a healing of a suppurating tuberculous gland which attaches itself to the esophagus.

The author believes that pouches at the upper end of the esophagus are embryological in origin, and should be treated by the two stage external operation.

Strictures resulting from the swallowing of caustics are treated by appropriate bougienage.

The author discusses no foreign body found in the esophagus other than the open safety pin with the point upward. If the pin cannot be closed with any one of the several safety pin closers on the market, it should be pushed into the stomach and watched by X-ray at frequent intervals. The pin may remain in the stomach straddling the pylorus. In such a case the pin must be removed surgically. In most cases the pin leaves the stomach promptly, and, within a week is recovered from the bed pan.

The author professes a sort of helplessness about carcinoma of the esophagus. He has seen some good results from massive doses of X-ray, and is hopeful that surgery will soon have more to offer.

A few patients with the Plummer Vincent syndrome have been seen by the author. That syndrome connotes secondary anemia with a history of long standing dysphagia and a smooth tongue. The treatment is appropriate bougienage. Ulcer of the esophagus is rare in the author's experience. He believes that it should occur in the lower part of the esophagus, and can be diagnosed best by X-ray.

Congenital shortening of the esophagus occurs rarely; shortening may result from the contraction of fibrous tissue following caustic burns. Septa may occur across the esophagus dividing it into several segments. Rupture and

dilatation of these septa must be done very carefully to avoid rupture of the esophagus.

It is the author's belief that in the condition called cardiospasm there is actually no spasm at all, but that there is a backward bend of the esophagus with a twisting and fibrosis of the esophageal wall at the crural canal.

During the course of acute and chronic infections, as well as during the course of infections in organs adjacent to the esophagus, marked involvement of the esophagus may occur. It seems then that fibrosis and subsequent stricture of the esophagus may occur at any point.

The author points out that esophagoscopy is not an entirely harmless procedure. It carries a mortality of 1.5 per cent.

Twenty-four figures accompany the article.

ABELL, I.

*The Diagnosis and Treatment of Diverticulitis and Diverticulosis. Surgery, Gynecology and Obstetrics, Vol. 60, No. 2A, February 15, 1935, pp. 370-377.*

Diverticula have been described as congenital or true, and acquired or false, the former containing all of the coats of the intestinal tract, the latter representing protrusions or herniations of the mucous and submucous coats through apertures in the muscularis. Diverticula may be found at all points in the intestinal tract from the pharyngo-esophageal junction to, and including, the rectum. They occur singly in the upper part of the digestive tube, while in the lower part, particularly the left half of the colon, they may be very numerous. They are found most frequently in middle aged men.

Pulsion diverticula of the esophagus are seen most frequently at the level of the lower border of the cricoid cartilage. The history of their development is characteristic. Their size and extent may be readily determined by fluoroscopic examination. Curative treatment consists in extirpation of the sac in a one-stage or two-stage operation followed by periodic dilations of the esophagus.

Diverticula of the lower end of the esophagus, when associated with cardiospasm, are best treated by treating the cardiospasm.

Diverticula may occur in any part of the duodenum. They are in the jejunum, and are found in the ileum usually as a Meckel's diverticulum. The retention and decomposition of food particles in a diverticulum will lead to distention, irritation and inflammation, which requires treatment. The diagnosis of diverticulitis in a typical or rare situations is usually made after X-ray examination, or at operation. If a single inflamed diverticulum is present, it should be excised. Diverticula are observed far more frequently in the colon than elsewhere in the intestinal tract. Autopsy records show the presence of diverticula in 5 per cent of all subjects over 40 years of age. They are most commonly found in the sigmoid and descending colon, while in 85 per cent of the cases the distribution of diverticula is throughout the entire colon. Occasionally diverticula are found in the appendix where they project from the lumen into the tissues of the meso-appendix.

Granting the presence of diverticulitis one of several results may follow: namely, resolution; perforation with resultant peritonitis and its sequelae; thickening of the gut wall, and its mesentery, so that obstruction of varying degrees results. Treatment during the acute stages, when the condition is understood, is medical, while treatment of the various complications is surgical. An obstructing mass which cannot be differentiated from carcinoma should be explored surgically and treated appropriately.

Nelson M. Percy, Chicago.

CHURCHILL, E. D.

*Esophageal Surgery. Surgery, Gynecology and Obstetrics, Vol. 60, No. 2A, February 15, 1935, pp. 417-423.*

In the author's experience with the surgical treatment of carcinoma of the lower end of the esophagus the procedure described by Sauerbruch was found thoroughly practical. By an extra pleural approach the diaphragmatic pleura is stripped off, and the diaphragm incised radially from the esophageal hiatus. The growth is mobilized and the stomach drawn upward through the diaphragm. The esophagus is severed from the cardiac end of the stomach and closed. The entire mass is now placed into the stomach by a modified Witzel procedure. This operation is satisfactory and not overly difficult, but as a one stage procedure it is too extensive. If the stomach is mobilized, and the absence of hepatic metastases determined at a previous laparotomy it would be much less extensive. The author proposes such modifications.

The construction of a new esophagus from the skin of the thorax by the method of Rovsing is a surgical feat that will certainly be of increasing use in the future. Although it was first described in the treatment of strictures, it may be used in the treatment of carcinoma also.

The author reports one case of mediastinal abscess which was drained successfully by an extra pleural posterior approach. In the treatment of intractable severe cardiospasm the author has employed esophagogastric anastomosis successfully in two cases.

Five figures and a bibliography accompany the article.  
Nelson M. Percy, Chicago.

FEY, A., AND CUBBINS, W. R.

*Acute Mechanical Intestinal Obstructions. Mortality with and without Enterostomies. S., G. and O., Vol. 60, No. 3, March, 1935, pp. 738-745.*

The authors present a study of 241 cases of "acute mechanical intestinal obstruction" from the files of the Cook County Hospital occurring between 1922 and 1931. Only those cases which were operated on have been studied. Cases of obstruction secondary to carcinoma, pelvic abscess, or strangulated external herniae are not included in this series.

Adhesions forming bands or kinks accounted for 74 per cent of the cases. Intussusception, internal herniae, and Meckel's diverticulum were causes in many cases. Certain other rarer conditions were also found.

The cardinal symptoms presented by these patients were pain, nausea, vomiting and constipation. Auscultation will show peristalsis to be most active at the height of the pain. Distention of the abdomen is not always present, nor is peristalsis always visible. The results of enemata are of little or no diagnostic value. Elevation of temperature, even in the presence of gangrenous bowel, is an uncommon finding. The pulse rate varies in direct proportion to the toxicity of the patient. The degree of leukocytosis is not a dependable guide as to the state of the bowel wall.

The mortality in this series is 42.7 per cent. In the few cases in which enterostomy was done and the obstruction relieved, the mortality was as high as in those cases in which resection and anastomosis for gangrene was done. It seems that resection and anastomosis is the procedure of choice in all but a very few cases.

Death results from damage to the bowel wall due to distention and strangulation. The exact manner in which death occurs is still in doubt, but the pertinent and essential facts are that it follows decreased viability of the bowel.

The authors conclude that enterostomy, drainage of the bowel, and gun barrel fistula have not reduced the mortality in this series of cases. The administration of isotonic salt solutions intravenously and hypodermically is a life saving measure in many of these cases.

Four tables and a bibliography accompany the article.

COLLIN, E. N., AND JONES, T. E.

*Benign Stricture of the Intestine Due to Irradiation of Carcinoma of the Cervix. S., G. and O. Vol. LIX, No. 4, Oct., 1934, pp. 644-649.*

In a series of 422 cases of carcinoma of the cervix treated with adequate and proper doses of x-ray and radium radiation, the authors found six cases with benign stricture of the intestine. In five cases the stricture was in the sigmoid, too high to be seen on sigmoidoscopic examination, while in one case the stricture was in the ileum. On fluoroscopic examination the lesions resemble the infiltrating type of carcinoma but with an hour-glass deformity showing a gradual change from the normal to the abnormal gut. The lumen of the intestine usually has a conical shape on each side of the lesion. Microscopically the constricted portion of the bowel shows changes similar to those previously described as being due to the action of roentgen rays and radium on the gastrointestinal tract.

The authors believe that "irradiation stricture" of the intestine should be suspected in any woman who develops unusual abdominal symptoms, particularly if they simulate intestinal obstruction several months or even years subsequent to irradiation therapy for carcinoma of the cervix. Minute inquiry should be made concerning the immediate post-radiation sequelae. In all of the cases reported having sigmoid lesions there was a history of tenesmus with bloody and mucoid stools for three weeks or longer following the irradiation therapy.

Such a complication of irradiation therapy can be prevented by changing the position of the intestines in relation to the source of radiation during actual time of treatment. Unless the intestines are fixed by adhesions, or by existing inflammation, they may be made to move away from the source of radiation by changing the position of the patient. The authors recommended the Trendelenburg position.

The importance of recognizing these lesions lies in the fact that they might easily be attributed to metastatic carcinoma in which case a hopeless rather than a hopeful prognosis would be given. The authors feel that this rare complication of the well proved present day efficacious irradiation therapy should not constitute a retarding influence on such therapy since it is so successfully treated by surgical intervention.

Three figures accompany the article.

ROSSER, C.

*Diothane in Surgery of the Anal Canal. A Clinical Survey of One Hundred Cases. S., G. and O. Vol. LIX, No. 5, Nov., 1934, pp. 820-823.*

The author reports the results of a series of 100 cases operated upon for haemorrhoids, fissure or other minor lesions of the anal canal using Diothane infiltration alone, or in conjunction with low spinal anaesthesia. Diothane may be used as a lateral block anaesthesia alone, in which case the patient experiences a stinging sensation for a few minutes before anaesthesia is established, or it may be injected in the same manner, or less extensively after anaesthesia has been established.

The advantages of using Diothane are that the anaesthesia lasts for 48 to 72 hours, that sensation returns very gradually, and that the period of painful sphincter spasm following other anaesthetics is entirely avoided. The disadvantages are that there is a slightly greater tendency to tag formation post operatively, and the occasional formation of apparently sterile chemical abscesses. No constitutional reactions to the drug were noted. The author feels that further experience with the drug will establish a technique giving more uniform results.

N. M. Percy, Chicago.

## SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### PASSAGE OF NATIVE PROTEINS THROUGH THE NORMAL GASTRO-INTESTINAL WALL

THE ingestion of protein foods would give us little concern were they simply broken down into their component amino acids and thus absorbed into the body-economy to play the important rôle which they do. It is known, however, that during protein digestion certain of the soluble albumins and globulins, particularly those which are consumed raw, will at times escape digestion and enter directly into the blood stream and there act as totally foreign substances to give rise to a group of allergic syndromes expressed in such *bizarre* manifestations as prurigo, urticaria, eczema, angioneurotic edema, asthma, and gastro-intestinal disturbances such as vomiting, diarrhea and colic. Some investigators have placed migraine, certain ocular disturbances, and even epilepsy in this category. It is conceivable also that the escape of undigested proteins through the gastro-intestinal wall and the passage of their higher degradation products might also give rise to serious vascular changes and kidney involvements. Prolonged excessive indulgence in protein foods might perhaps result also in a marked reduction in the functions of the proteolytic enzymes. The problem, therefore, of the passage of unchanged proteins through the normal gastro-intestinal wall is not one of purely academic interest but becomes of concern to all physicians.

Inspection of the literature shows how hard it has been to approach the problem experimentally. While there is sufficient evidence to warrant the assumption that unsplit antigens enter the blood stream directly from the gastro-intestinal tract, (1), (2), (3), (4), (5), (6) the majority of the investigators have concluded that such a passage becomes possible only when the permeability of the gastro-intestinal wall is increased by abnormal or pathological conditions (7), (8), (9), (10). Stasis, the excessive flooding of the intestines with protein foods, lessened activity of the digestive enzymes, altered conditions of the intestinal mucosa and an abnormal permeability of the intestinal wall in new-born and suckling infants have been described as possible contributory causes.

The problem recently has been attacked again by Ratner and Gruehl (11) who felt that inadequate consideration had been given to the possibility that proteins in a native state may pass through the normal intestinal wall during the course of normal digestion. After surveying the literature Ratner and Gruehl were inclined to doubt the commonly held view that it is only when abnormal or pathological conditions of the intestinal mucosa are present that unchanged proteins enter the blood stream. It seems that the earlier investigators failed to take into consideration, among other factors, the nature of the proteins which they used, the quantities which they administered, and the limitations of the methods employed to detect the presence of unchanged protein in the blood stream. Actu-

ally, the difficulties of detecting foreign proteins and antibodies by the precipitin method are considerable, not only because the material is so greatly diluted in the blood and urine, but because ingested foreign proteins absorbed through the intestinal tract leave the blood stream as a rule within a few hours, and disappear from the urine within 24 hours. In the earlier experiments small numbers of animals were generally used, and artificial factors, such as trauma, were often introduced.

In their experimental work which was done largely on guinea pigs, Ratner and Gruehl utilized the anaphylaxis test as the biological method of choice to determine whether native antigens entered the blood stream directly. Animals were sensitized by feeding to eliminate any traumatization of the intestinal wall. Cow's milk was given. Although this is foreign to the natural diet of the guinea pig, it is non-irritating, non-toxic and well tolerated by the animals. The experiments showed that at least 50% of a large series of animals could be sensitized through natural ingestion, and that the passage of the antigens would take place in adult as well as in new-born animals. Though a single small dose would occasionally sensitize, fairly large amounts were necessary to sensitize animals with any degree of regularity.

Using human subjects Ratner and Gruehl found evidence to indicate that proteins from foods such as cottonseed, which are foreign to the diet, and even milk can enter the circulation. This occurred in normal persons and allergic patients and in adults as well as children. These observations corroborate the findings of Schloss and his co-workers (12) who, using immunological methods, showed that ingested native proteins from milk, eggs and almond will enter the blood of normal young children. Walzer *et al.* (13) using the Prausnitz-Küstner test, found that 88% of the normal adults whom they studied showed the presence of proteins of egg and fish in the blood after the ingestion of these foods. Walzer particularly stressed the physiological nature of this passage and because of its frequent occurrence in the average person, he believed it to be a normal phenomenon.

In view of these now several times repeated observations, the question may well be raised why all persons do not get sensitized to proteins. Ratner and Gruehl offer the following explanation. The body is provided with certain defensive measures which tend to impede the entrance of proteins in an unchanged state into the blood stream and tissues. These measures include the impermeability of the intestinal mucosa, the digestive enzymes, specific antibodies, and the excretory functions of the kidneys. Denaturation of proteins by heat and other culinary processes also aids the body in this defense. When antigens enter in small amounts and at frequent intervals, as has been shown by Wells (14), Schloss (12) and Laroche (15) an immunity is established. On the other hand, if anti-

gens enter in particularly large amounts and at infrequent intervals, then the animal or man may become profoundly sensitized and the subsequent ingestion of even small amounts of antigen is likely to produce allergic manifestations, shock and even death. It is possible that the normal absorption of small amounts of unchanged proteins may serve the useful purpose of constantly maintaining the body in a state of immunization against the ingestion of too large an amount of these substances. When the defense mechanism fails to act and antigens enter the blood stream in large amounts disease-producing hypersensitiveness may result.

Bret Ratner, New York City.

Clinical Professor of Pediatrics and Lecturer in Immunology, New York Univ., College of Medicine.

#### BREVITY

THIS Journal endeavors to make its columns available to clinicians and investigators who have something valuable to present to its twenty thousand, monthly readers. Further, the Journal is making a determined effort to print submitted, worth-while manuscripts promptly.

Each issue of this publication contains in excess of 60,000 words of text, an unusually large volume of material in a monthly periodical. This generous allowance is made possible by the Journal's large page. However, even this issue-size has become too limited to take care of manuscripts according to our policy. In consequence, constantly a large number of excellent papers await allotment to future numbers.

Upon analyzing certain submitted manuscripts, one finds them, to put it mildly, extremely "wordy." Not alone do some authors attempt to cover too much ground but, in doing so, they are very generous with language. Too literally do certain authors interpret Carlyle's "Produce! Produce! Were it but the pitifulest, infinitesimal fraction of a product, produce it, in God's name!"

Reviews of literature, case histories, long tabulations, musings and deductions—all, to be sure, of vast interest to individual authors, even if not necessary or fascinating to the general, or even the special reader—demand a veritable tower (not infrequently "Babel" in character) of words and consume valuable page space, space costly to print and, we admit, jealously surrendered when a huge pile of manuscripts cries out for placement.

In order that the Journal's policy of prompt publication, high standard of text and sightliness of format be maintained, we urge upon those who contemplate submitting manuscripts, that, before sending them, they re-read them frequently with the object of eliminating every unnecessary word, sentence, tabulation, chart, illustration or literature-reference which adds nothing to originality, interest, medical progress or the sum total of the world's knowledge.

If each author consistently follows these suggestions, our pages will be able to carry more and varied types of manuscript, prompt publication will be possible, each article will "earn its space" and—a practical angle—writers will have to pay considerably less for reprints.

We are passing on these suggestions to the Members of the Editorial Council and the Publications' Committee with the hope that, when articles are appraised for acceptance or rejection, they will consider in their decisions the weight of *brevity* as well as the significance of clinical or scientific data.

F. S.

## SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

*"Body Mechanics in the Study and Treatment of Disease,"* by J. E. Goldthwait, L. T. Brown, L. T. Swain and J. G. Kuhns.—J. P. Lippincott Co., Phila., 1934.

IT is interesting to see how a group of four orthopedic surgeons look upon chronic diseases of various kinds, including not only those of the muscles, bones and joints, but also those of the abdominal viscera, heart, lungs, blood, metabolism, nervous system, etc.

The authors stress the importance of body types and posture; the relation of the bones to each other and their proper alignment, especially in the spine, thorax and pelvis; the position and tone of the diaphragm and muscles of the belly wall. They show how the abdominal viscera are supported by the diaphragm above and how the flat chest pushes the upper abdominal organs down, and how the lax belly wall favors this.

They have done a useful service in emphasizing the importance of body build and good posture, not only in "orthopedic cases" as usually understood, but in any sort of chronic medical patients so that the spine, pelvis and joints of the leg and foot may bear the weight of the body easily and avoid strain, so that the thorax shall be large and deep enough to give plenty of room for the ventilation of the lungs, so that the abdominal organs are kept in good position, their blood supply not interfered with, and good function preserved.

Clear directions are given about treatment, muscle building, exercises, posture and braces which are well illustrated by sketches. A series of case reports is included, showing how good results were obtained in various types of cripple and viscular disturbances. In reading this book we should remember that it sums up the experience of men who have done excellent work in bringing back a large and difficult group of physically inferior persons to comparative health.

On the other hand we meet various opinions and theories scattered through the book, which well may be criticized. In order to stress the value of their orthopedic work the Authors say in the preface, "No one who has studied the work of the various hospital clinics can fail to be impressed with the relatively small number of patients suffering from chronic disease that are accepted for treatment or that are receiving benefit from the treatment given". This seems neither polite nor true when one recalls the countless multitudes of chronic patients treated in our medical outpatient departments and wards, and in the many special clinics for chronic diseases such as tuberculosis, nephritis, diabetes, diseases of the heart, gastro-intestinal disease, thyroid, metabolism, etc., etc.

The rôle of orthopedics seems exaggerated at times. In the preface the question is asked, "Is it not possible that much of that which concerns chronic medicine has to do with the imperfect functioning of sagged or "misplaced organs"? and the answer is given. "In the broader knowledge of the special structure of

the individual—and of the varying mechanics of the body the solution of the problem of chronic disease is largely to be found."

Orthopedic treatment holds a large and honorable place in medicine, but it does not play the *major* part in "most chronic diseases". It seems possible after all that "the chronic patient" who is continually referred to throughout the book must be one of the comparatively limited group who go to the orthopedic surgeon and not "the chronic patient" of a general medical clinic.

We will quote a few examples of questionable opinions and theories in the field of diseases of the digestive organs. The right shoulder pain in gall-bladder disease is explained by the drag on the vagus nerve by the low diaphragm. No figures are given to show that this pain is more common or found only in gall-bladder cases with ptosis. Again, "Since passive congestion and chronic irritation are two of the factors which may lead to cancer, the potentialities of faulty Body Mechanics in the abdomen are serious when it is realized how commonly malignant disease is found there." No figures are given showing any relation between ptosis and abdominal cancer.

Again, "The pancreas is subject to pressure by the stomach and coeliac axis. Its internal secretion may be deranged, and lead to chronic glycosuria, ptosis being the original cause of such dysfunction." Some statistics to prove the frequency of glycosuria in ptosis would be welcome but none are given and it seems contrary to clinical experience.

Again, "The stomach should be above the navel". They seem ignorant of the work of Moody, Van Nuyss and Chamberlain, who showed clearly ten years ago that in 80% of 600 normal healthy adults the stomach reached 1 to 3 inches below the inter-iliac line. Finally there is the question of cause and effect. Do we not often find that the abdominal organs sag because the person is slender, weak and delicate, and not always that the person became weak, thin and sickly because his organs "sagged"?

It is a stimulating and interesting book and many medical problems are studied from a new point of view, but it would be more convincing in parts if these *Authors* did not ride their hobby so vigorously, and if new and striking theories had some statistics to back them up.

The book work is excellent and the illustrations clear and well chosen.

Franklin W. White, Boston.

*Methods of Treatment*, 5th Edition; by Logan Clendening, M.D., illustrated; Published by the C. V. Mosby Co., St. Louis, Mo., 1935. Price \$10.00.

WHILE no one can deny Dr. Clendening the right to disregard any critic who finds fault with the omission of what the latter may think should appear in the text, the criticism still holds but in no way detracts from the merits of his book. The author states

that his efforts are mainly the results of his own experience.

One clinician may prefer dilaudid as a sedative, another digifortis, digifolin or digalen as cardiac stimulants, still another may prefer anayodin for amebiasis, none of which is mentioned in the text, to those recommended by the author for their particular purposes. Such omissions by no means, however, lessen the value of the book. Its scope and extent, its literary qualities, the notes of historical value, the discussions

in which indications for various drugs are given, based upon physiological and clinical requirements should, as it has in the past, continue to make the volume a valuable addition to the physicians' library and office. It is a combination of materia medica and therapeutics by Dr. Clendening and others in a way that make the whole readily usable. There are many illustrations, charts, diagrams, and medical references and the printing is excellent.

Leon Bloch, Chicago.

## ABSTRACTS

SMITH, N. D., AND BROEERS, A. C.

*Melano-Epithelioma and Hemangio-Endothelioma of the Anus.* S., G. and O., Vol. 60, No. 1, Jan., 1935, pp. 74-77.

The authors report four cases of melano-epithelioma and hemangio-endothelioma of the anus. In one case of melano-epithelioma the tumor was found on the anterior anal wall. In spite of complete excision of the tumor and irradiation therapy, the patient died with wide-spread metastases 21 months later. The second case of melan-epithelioma was discovered during the routine microscopic examination of tissue removed during an operation for hemorrhoids. One hemangio-endothelioma was found in the anterior margin of the anus. It presented the appearance of a thrombotic hemorrhoid but caused no discomfort. Microscopic examination revealed its true nature. This patient was given 330 milligram hours of radium irradiation in the healing wound; three months later no evidence of a recurrence was found. The second hemangio-endothelioma was discovered during the routine microscopic examination of tissue removed during the excision of an anal fistula.

The prognosis in cases of melano-epithelioma is grave, but it is not beyond reason to expect that the tumor could be discovered early enough and completely excised. The prognosis in cases of hemangio-endothelioma is good; they grow less rapidly and metastasize less frequently.

Two of these cases prove the value of routine microscopic examination of tissues removed at operation.

Four figures accompany the article.

N. M. Percy, Chicago.

E. A. DANIELS.

*Early Diagnosis in Rectal Cancer and Prognosis on the Basis of Dukes' Classification.* Can. Med. Journal, Dec., 1934, p. 612-616.

Early rectal cancer gives few and indefinite signs, when there are definite signs and symptoms it is inoperable. The lesion always begins in the mucosa and extends through the rectal wall into the perirectal tissues. Dukes' classifies growths A, B or C, according to degree of direct spread, A being limited to the wall, involving but not beyond the muscularis, B extends into the perirectal tissue, but there is no glandular involvement; in C the regional lymphatics are involved. Pain and bleeding only occur with involvement of the extra-rectal tissues and the cutting off of the circulation to the growth causing ulceration.

The prognosis in rectal cancer is grave only in late cases, the C cases of Dukes' classification, the disease remaining localized for a long time. Vague symptoms of, change in bowel habit, backache, frequency of urination

call for rectal and proctological examination. With the proctoscope from the appearance of the growth, whether sloughing and friable or not, or whether fixed or not, one can get some idea of what stage has been reached.

Dukes examined histologically 215 specimens removed at operation; of these 18% were A cases, and 47% were C cases. Sixty cases were followed up after excision. Of these 15 were A, 24 were B and 21 were C cases. Three years later 86% of A cases were alive and well, 73% of the B cases, and 19% only of the C cases.

The classification would seem to be a very useful means of estimating prognosis.

R. H. M. Hardisty, Montreal.

H. O. OUGHTERSON AND M. T. SHELTON.

*End Results in the Treatment of Carcinoma of the Colon.* Yale Jour. Biol. and Med., 1934, VI, p. 435.

The authors conclude, from their own experience in the New Haven Hospital that cancer of the colon is being more effectively treated than either cancer of the stomach or rectum. A higher percentage of patients with cancer of the colon is being admitted to Hospitals in New Haven than those with cancer of the stomach, though not as high as those with cancer of the rectum. A higher percentage of patients with cancer of the colon are seen earlier, and the mortality at operation is lower. These factors are assisted by slower growth of the tumor and the tendency to late metastases. More than 42% should have an opportunity for a radical attempt at cure. A 2 stage radical operation is important. The radical operation for cancer of the colon results in a higher per cent of 5 year cures than does operation in any other portion of the intestinal tract.

Franklin W. White, Boston.

K. BLOND.

*The Pathology and Therapy of the Varicose Disease of the Rectum.* Wiener Klin. Woch. No. 47, 1934.

Nodules, fissures, periproctitis and pruritus of the anus are only different stages of congestive diseases of the rectum. The fistulas are veins of the hemorrhoidal plexus that become infected and filled with thrombi. If situated at the line of demarcation between the mucosa and the skin a fissure is the result. A dissection of the routes of the fistula should be done. In other cases, Pacqelinisation is necessary. An accompanying pruritus and almost always disappears after eliminating the underlying pathology. Such anal fissures or fistulas may often become starting lesions for propagation of secondary infections into the intra and extrahepatic bile ducts. The route for invasion is the hemorrhoidal plexus.

M. E. Gabor, Milwaukee.

## SECTION XII—"The Clinic"

### An Instance of Marked Abdominal Distension with the Probable Etiologic Factors Being Abnormal Endocrine Function\*

By

GEORGE B. DORFF, M.D.  
BROOKLYN, NEW YORK

**T**HE interrelation of the somatic and the skeletal systems and the endocrine systems must always be borne in mind when one is confronted with evidences of developmental arrest in the child. Symptoms seemingly of a non-endocrine nature which are accompanied by such somatic or skeletal maldevelopment should always be carefully evaluated for the possibilities that such symptoms may be manifestations of endocrine dysfunction.

One such case, where the complaint was abdominal distension, came under my observation. It is here presented as an example of the endocrine factor involved and the significance of that involvement from the differential and therapeutic standpoints. So that cognizance of these types may be taken and proper therapy administered as early as possible, this case is reported in detail.

#### CASE REPORT

T. D., an Italian boy, aged 6½, was referred to the hospital† on September 5, 1934, with the complaints of pain, and enlargement of his abdomen. This enlargement had been noted by his mother for the past year; however, it had become more marked in the past two months. There was no concomitant nausea, vomiting or temperature. The abdominal pain was not acute and had its recent acute inception one week previous to admission.

The patient was of a full term normal delivery, and was the last of nine

children. He was of good size at birth; was breast fed only for a short period and then was placed on bottle feedings. Cod liver oil had not been given until the age of 1½ years; it had been taken until the age of 2. The only illness, measles, had occurred in early infancy. There was no history of constipation or diarrhea, although the patient often would have two to three bowel movements daily. His diet was varied, including fresh fruits and vegetables. He had grown, however, very slowly. The father had died of hypertension, at the age of 44 years; and four siblings died of pneumonia. The mother was apparently well.

An examination of the patient by the writer on September 5, 1934, exhibited a dwarfed, undernourished, fairly alert boy who presented marked abdominal distension. There was pallor, but no apparent jaundice. The head was not enlarged; his hair and skin were not dry. The eyes reacted to light and accommodation; the deciduous teeth were in bad condition; there were many carious teeth showing hypoplastic enamel; the sixth year molars were present but also lacked enamel. The tonsils were enlarged. There were some enlarged cervical glands. The bony chest was negative. The heart sounds were rapid but normal in character. The lungs were clear.

There was a marked distension of the abdomen which tended to bulge laterally. The umbilicus was flattened and the abdomen was generally tympanitic. There were no palpable masses nor was there any shifting dullness. Peristaltic waves could be made out and induced. Some very slight abdominal tenderness was present. Rectal examinations proved somewhat painful but no masses were felt (Fig. 1).

The extremities were not distorted in any way, and were proportional to the

rest of the body. His height on admission was 38 inches (normal 44.5-47.7 inches). His weight was 34 pounds 12 ounces (normal 41.0-50.8 pounds). Two small testes were present in the scrotum; the penis was small.

An admission diagnosis of "megacolon" was made with the possibility of its being congenital (Hirschsprung's megacolon).

Laboratory studies were as follows: (October 2, 1934):

|                        |         |
|------------------------|---------|
| Haemoglobin (Sahli)    | 46%     |
| RBC                    | 3.6     |
| WBC                    | 9,400   |
| Platelets              | 300,000 |
| Staff Granulocytes     | 3       |
| Segmented granulocytes | 60      |
| Lymphocytes            | 24      |
| Monocytes              | 11      |
| Eosinophiles           | 1       |
| Basophiles             | 1       |

There were marked poikilocytosis and anisocytosis but no nucleated red blood cells. Dr. Charles Feingold of the Haematology Department was of the impression that there was a marked hypochromic anemia, probably nutritional.

A fasting blood analysis revealed the following:

|                  |         |
|------------------|---------|
| Glucose          | 86 mgs. |
| Urea N.          | 8.5     |
| Creatinine       | 1.0     |
| Chlorides        | 587     |
| Cholesterol      | 140     |
| CO <sub>2</sub>  | 47      |
| Serum Calcium    | 11.5    |
| Serum Phosphorus | 3.8     |

The Wassermann test was negative. The Mantoux 0.1 mg. and increased to 1.0 mg. was negative for tuberculosis. A casual urine examination showed no abnormal findings. A phthalein functional test showed 60% elimination for the first hour and 15% in the second hour—a total of 75%. A Mosenthal test on two occasions returned the following: (November 5, 1934):

\*From the Endocrine Clinics of the Department of Pediatrics of New York University, College of Medicine, and the Children's Medical Service of the Third Medical Division, Bellevue Hospital, and Beth-El Hospital.  
Presented before the New York Endocrinological Society February 27, 1935.  
Submitted April 16, 1935.

†I am indebted to Dr. Harry R. Litchfield of the Pediatric Service of Beth-El Hospital for the opportunity of studying this case.

Fig. 1. Age 6½ years. Note abdominal distension.

|                   | S A. M. | 10 A. M. | 12 N. | 2 P. M. | 4 P. M. | 7 P. M. | 10 P. M. |

| November 9, 1934: |         |          |       |         |         |         |          |
| Amount            | 30 cc.  | 15       | 25    | 10      | 25      | 28      | 25       |
| Amount            | 1033    | 1035     | 1034  | ...     | 1030    | 1034    | 1023     |

Examination of the stool on several occasions showed it to be bulky, greyish in color and foul smelling. Amylase, and a normal amount of fat were present; ova, and *B. dysenteriae* were absent.

A water test for any parenchymal liver damage (Adlersburg) showed an intake of 1000 cc. of water and an output of 985 cc. of urine (normal). Several basal metabolic readings were in the neighborhood of plus 100. Obviously, the rate, as estimated, was erroneous.

An X-ray examination at the time of admission, September 6, 1934, by Dr.

Max Dannenberg, as revealed by the flat film taken in the erect position, disclosed a considerable amount of gaseous distension with evidence of fluid levels in the intestinal loops.

Further examination after a barium, colon enema showed no definite evidence of obstruction or true intrinsic defects. There were a generalized atony and dilatation of the colon and at the flexures (Fig. 2).

The bones of the skull were normal. The sphenoids were clouded. The sella turcica was normal.

A roentgen study, September 22, 1934, (by the writer), of the osseous

development, showed the presence of four small carpal centers in each hand. The distal epiphysis of the left ulna was pin point, and that in the right was absent. The epiphyseal nucleus for the head of the radius was absent (the average normal appearance is at 5 years—patient was 6½ years). There was no evidence of any rachitic changes. There was a moderate generalized haliteresis present in the diaphyses of the long bones, particularly in that of the knee and elbows, and some in the hands. Transverse lines of arrested growth were present about ¼" below the distal part of the femur and at the distal part of the tibia. In all, bone development was retarded about two years.

*Diagnosis:* Because of the absence of abdominal distension or gastro-intestinal symptoms in early infancy, and the locally insufficient dilatation of the intestinal loops as is characteristic of

Fig. 2. (Hand) Aged 6½ years. Eleven weeks after thyroid medication. Note retarded centers of ossification in the carpus, and the presence of the pin point epiphysis of the ulna which was absent on admission.

Hirschsprung's congenital megacolon, this latter diagnosis was discarded and the diagnosis of hypothyroidism was substituted. This diagnosis of hypothyroidism was based on the findings of dwarfism, atonic intestinal tract, anemia, and marked delay in osseous development.

Fig. 3. Left (7208). Note dilatation and absence of haustral markings.

**Treatment:** The patient was placed on a full hospital diet and was given desiccated thyroid, 1½ grains daily, (September 14, 1934.) This remedy was exhibited for about eleven weeks.

It was noticed that, while the patient was in the hospital, he had a voracious appetite at all times and constantly had to be given extra portions of food. When these larger meals were given, the abdominal distension became more prominent; however, there occurred no such intestinal upsets as diarrhea, nausea or vomiting.

On November 30, 1934, after 11 weeks of thyroid therapy, the patient was placed on a standard, three day, Schmidt's test diet. During this time, the standard diet with some slight modification was given, and the stool therefrom was collected for examination.\*

Following is the analysis of the stool which was examined after it had been collected over the test period for the Schmidt diet:

"The stool appears soft, bulky, grayish and unformed; on microscopical examination there is present much cellular debris and an occasional starch granule; no undigested muscle-fibers are visible. There are moderate amounts of neutral fat, larger amounts of fatty acid and soap. After the addition of 30% acetic acid and heat, the specimen shows large amounts of neutral fat globules."
